PACKING

for

STEAM (especially high pressure superheat)

and

COMPRESSED AIR

has a world-wide reputation for showing a greater economy over lower priced packings because it is made of materials that give long satisfactory service.

It is cheaper in the long run to use a packing that has the quality if real economy in operation is to be considered.

BRAIDED round and square for rods. Sizes ⅛″ to 2″ by sixteenths. Put up in dust-proof boxes of about 5 lbs. each.

TWIST for small valves—each strand is separately lubricated, and therefore a perfect packing in itself. By unstranding any size valve may be packed from one spool. Comes in sizes ⅛″, 3/16″, ¼″, 5/16″, ⅜″, 7/16″ and ½″ on one-pound tin spools in dust-proof boxes.

Send for free working samples to test under your own conditions. It will pay you to know how long "Palmetto" lasts in service.

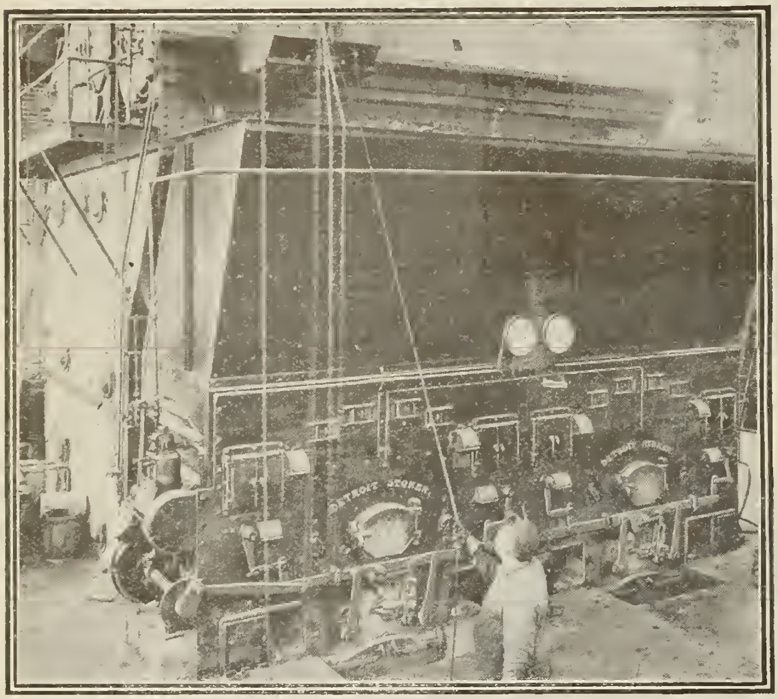
BRANTFORD, ONTARIO, CANADA

\$1000^{00} or More Saving per Year by Use of Cheaper Fuel Alone with one Detroit V-Type Stoker—



Detroit "V" Type Stokers and Stirling boilers.
Coal bunker built by Detroit Stoker Company.

The opportunities for effecting savings through the installation of Detroit V-Type Stokers are larger than are generally appreciated. Coal consumption in the average plant, for instance, is not less than 10 tons per H. P. year— that is 1000 tons of coal will be fired under a 100 H. P. boiler, 2000 tons under a 200 H. P., etc. As Detroit Stokers will burn successfully lower grades of fuel than can be used with hand firing, it is frequently possible to save a dollar or more a ton on the purchase price of coal alone, so that savings of \$1000 to \$2500 per stoker per year from this one source are not uncommon.

Of equal importance is the increase in overall boiler efficiency effected by the use of Detroit Stokers. Fifty-five to sixty per cent efficiency is a really high average for the typical hand-fired plant. After Detroit Stokers are installed efficiencies of seventy to seventy-five per cent are readily maintained. This means that with Detroit Stokers four tons of coal will produce as much steam as will five tons of coal in the hand-fired plant.

Remember that natural draft stokers may be profitably installed under both tubular and water tube boilers.

Send for your copy of the
Detroit V-Type Stoker

D K McLAREN LEATHER BELTING

There are Two Good Reasons Why

D. K. McLaren's Leather Belting gives such "trouble-free" service on the pulley—a service which means so much when transmission costs are considered.

The first is that only the **back portions** of the choicest hides, selected by experts, are used. All shoulders, necks and bellies go into the discard so far as D. K. McLaren's Belting is concerned.

The second reason is in the

Genuine British Oak Tanning Process

to which every inch of leather is subjected. This process should not be confused with the ordinary "Oak" process more often used in the Tanning of Leather. It is the one-time closely guarded secret of English tanners—a slow, expensive process, but one to which D. K. McLaren's Leather Belting owes its unusual toughness and pliability which gives it that "gripping power" for which it is so famous.

The Oak Leaf stamped upon every length identifies it —it's also your guarantee and is worth looking for.

Made From Back Leathers

The Best Part of the Hide

Only the choicest steers are selected for the making of this belting. It has quality through and through because only Back Leathers are used.

Increases Your Production

GUTTA PERCHA & RUBBER, LIMITED
TRADE PMS MARK
THE "RED RIBBON" BELT
TORONTO, CANADA

"P M S"

THE "RED RIBBON" BELT

Increases production by giving greater efficiency in transmitting the power that is so costly to develop, by minimizing "breakdowns" and stops for readjustments.

These are not mere idle claims, but actual achievements by "P M S" in many of Canada's leading plants. Greater adhesion to the pulley, great strength, even pliability, and remarkable resistance to the effects of heat, cold and moisture are the reasons for its success.

View of Canada Cement Company Building, Phillips Square, Montreal, Completed 1922.

Artistic, Fire-Resisting Buildings of Concrete

The new Mount Royal Hotel and the Canada Cement Company Building add to the architectural achievements of Canada's greatest city.

It is particularly gratifying to have Concrete and Concrete products aid in this accomplishment. The facing and stone trim, manufactured by the Canadian Benedict Stone Co., Ltd., in Montreal, is used on the Mount Royal Hotel. The same stone is used on the Canada Cement Company Building.

This manufactured stone is reasonable in cost as well as pleasing in appearance. It is being used in many of the important structures now under construction in Ontario and Quebec.

The foundation and floors of the new hotel are reinforced concrete and the Canada Cement Company Building is Concrete throughout.

These two beautiful structures are fire resisting—a most important consideration in a hotel and office building. Our confidence in the fire resisting qualities of the Canada Cement Company Building is evinced by our decision to carry no insurance whatsoever on the building.

**We have literature on the possibilities of Concrete in office buildings.
We shall gladly mail copies free to anyone interested.**

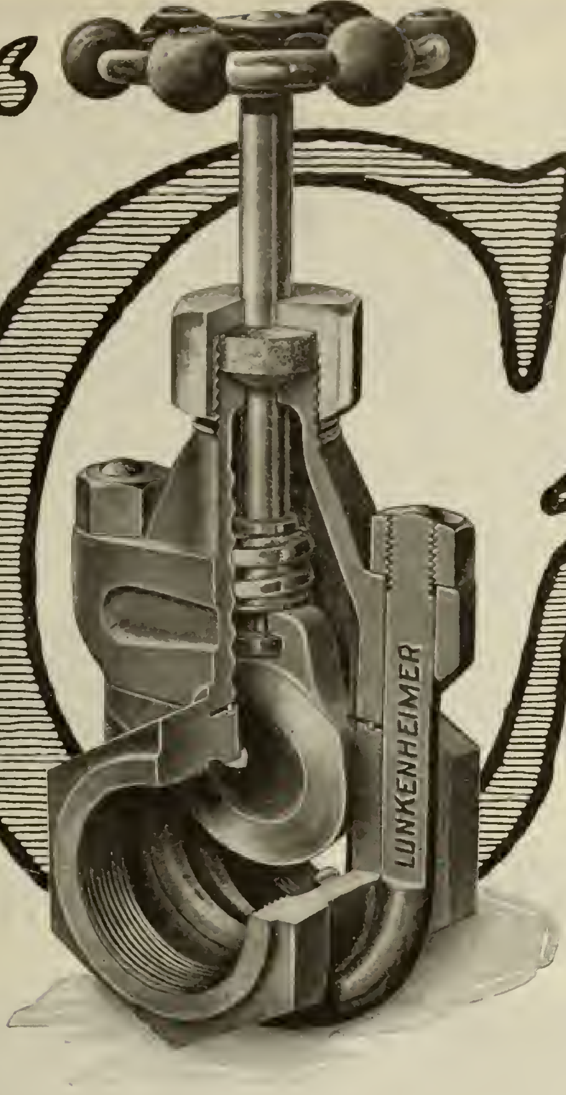
"Clip"



Gate Valves

An original Lunkenheimer development with a record of more than twenty years of success in service.

The simplicity of the design; the durability and the wide range of sizes and material combinations available peculiarly fits them for standardization in the low pressure lines throughout the plant. The Inside Screw type is recommended for pressures up to 100 pounds, while the Quick-operating type is good for 50 pounds.

Iron Body Bronze Mounted for handling Steam, Water, Oil, etc., and "All-Iron" for use with Acids, Alkalis, and other fluids which attack bronze alloys.

Specify LUNKENHEIMER and insist on getting the genuine. Booklet 505-DC covers the full range of types and sizes, together with description and list prices. Let us send you a copy.

YARWAY BLOW-OFF VALVES

THE YARWAY TANDEM

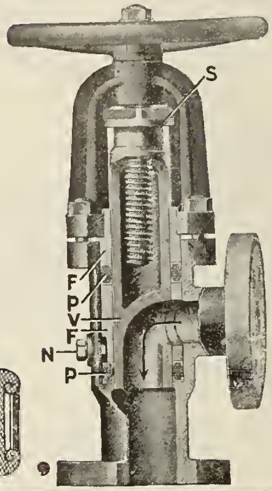
This is the ideal combination for blow-off service. The slow-opening plunger type Seatless valve can be depended upon to keep the line tight and prevent water-hammer, while the quick-opening lever-operated Double-Tightening valve may be used only in case of repairs or emergency.

THESE two valves — the YARWAY SEATLESS BLOW-OFF VALVE and the YARWAY DOUBLE-TIGHTENING VALVE— have given to thousands of power-plant men a new idea of the efficiency and service that may be reasonably expected from blow-off valves.

Both valves are fully described in Booklet B-410. A copy will be promptly mailed at your request.

YARNALL-WARING COMPANY
Mermaid Lane & Ardleigh St.,
PHILADELPHIA

207 St. James St., MONTREAL. 400 Penobscott Bldg, DETROIT.



YARWAY SEATLESS BLOW-OFF VALVE

After valve has closed, shoulder S on plunger V engages the loose follower gland F. A hard turn of handwheel then compresses packing P above and below the port, making an absolutely tight valve. This automatic method of tightening the packing is an exclusive advantage of the YARWAY SEATLESS BLOW-OFF VALVE. Set screw N prevents turning of gland F when handwheel is turned.

This valve has the unique feature of a sealing bushing on the inlet side, making it double-tightening on both sides of the gate. It conforms with the A.S.M.E Boiler Code and boiler laws of all States.

DE LAVAL TURBINE DRIVEN PUMPS AT TORONTO

THE De Laval geared steam turbine driven centrifugal pump has amply demonstrated its ability to handle water at the least cost, fixed charges as well as fuel cost being considered. Toronto has three units of this type in the John Street Station and two in the High Level Station, the aggregate capacity being 100,000 Imperial gallons per day, or about 5,000 water horse-power. The High Level Station pumps, shown above, have capacities of 20,000,000 gal. per day against 106 ft. and 7,500,000 gal. against 266 ft. Four 20,000,000 Imperial gal. per day motor driven De Laval pumps designed for 250 ft. head have recently been installed and accepted by the City of Toronto, after highly satisfactory acceptance tests. Over 150 municipalities and some 20,000,000 people on this side of the globe now depend for water supply on De Laval centrifugal pumping units. If you are interested in this subject, we will gladly send you our book W-100 "Ten Years' Progress in Water Works Pumps."

*"Lateral Retort" is a trademark — illustrated by this figure.

The arrows show the path of coal travel.

For the Plant with "Multiple Retort" Ideas and a "Single Retort" Appropriation—

THE advantages of the multiple retort type of stoker—higher efficiency and heavy overload capacity—make a universal appeal. As compared with other stoker principles the multiple retort type has just one disadvantage — its greater first cost.

Under certain conditions the greater first cost and installation cost of the multiple retort type becomes a serious drawback.

Right there is where the *"Lateral Retort"** Stoker fits in—it has made possible, for the first time, a multiple retort effect in a simple side-cleaning stoker—a stoker that costs far less than a multiple retort stoker; that requires no expensive provisions for installation; that is adaptable to old boilers because no basement space is required for ash pits.

The ingenious *"lateral retort"* principle insures multiple retort stoking in a simple stoker with only a few rugged moving parts.

Coal is first underfed to the large central retort by a steam driven ram. It is then underfed to the several *lateral retorts* by means of simple pusher rods, all of which are operated by a single auxiliary steam cylinder. From its entrance into the main retort until it reaches the dump plate, the coal is always *underfed*—an advantage heretofore possible only in stokers of the multiple retort type.

Learn how the *"Lateral Retort"* Stoker meets a hitherto unfulfilled need. Write for the new bulletin.

Showing asphalt mastic finish in the plant of the Avondale Ice Company, Cincinnati, Ohio.

Nonpareil Corkboard with asphalt mastic finish ironed on at the factory.

Asphalt Majestic Finish for Ice Storages

HERE is a finish that does stand up in ice storages and one that will protect your insulation permanently—asphalt mastic Nonpareil Corkboard. Asphalt mastic is not a mopped coating, but is ironed on at the factory, smoothly and evenly—approximately 1/8 inch thick. It is keyed into the board under pressure and contains no voids or air holes.

Asphalt mastic is impervious to air and moisture and so tends to prevent the formation of frost in and under the finish. Asphalt mastic is odorless. It will not run or peel at ordinary temperatures or crack when cold.

Asphalt mastic Nonpareil Corkboards are used for the finish course only. The edges of the coating are slightly beveled, leaving shallow V-shaped joints in the surface when the boards are erected. These are filled with mastic composition which is smoothed out and amalgamated with the mastic on the board by going over the joints with a heated iron. The result is an unbroken, airproof and waterproof surface. No other finish is required.

Asphalt mastic Nonpareil Corkboard is recommended for all ice storage rooms, for coil lofts and bunkers and for all cold storage rooms where excessive moisture is present.

Full Information will be furnished on request. Ask for a copy of the 152-page book, "Nonpareil Corkboard Insulation" and a sample which are sent free of charge.

"For Reliable Service give me YORK Equipment"

When the Operating Engineer of an Ice Making or Refrigerating Plant insists upon the Plant Manager buying York Ammonia Fittings and Supplies, he knows he is saving himself a lot of time and trouble and also reducing the operating costs of the plant.

He knows, because he has learned through past experiences of his own, or perhaps from another Engineer, that York Equipment is designed and made to meet the severest Service.

Surely, the man who is responsible for the operation of the plant, who sees and handles the equipment every day, should be best able to judge the merits of each piece of apparatus.

And the engineer out of justice to his employers and to himself, will recommend York Apparatus, which he realizes will give satisfactory results in actual service. That's why more York Ammonia Fittings and Supplies are sold each year than any other make.

There is perhaps no other concern of its kind in the world able to handle such a large number of orders or such a heavy volume of business.

A trial order will convince you of the Superior Quality of York Ammonia Fittings and Supplies.

FRICK Combined Refrigerating Machine

This machine fills the needs of dairies, groceries, meat markets, restaurants, hospitals, confectionery and floral shops, etc., for a simple and efficient small refrigerating plant.

The machine is manufactured in one-ton and two-ton sizes. It is a complete self-contained unit, including compressor, condenser, separator, receiver and connections mounted on one solid portable iron base as shown. It is completely assembled in one crate with motor and motor base in separate box, and can be taken through a 26-inch door without uncrating.

No foundation is required. The machine is as easily put in place as the ordinary counter or refrigerator, and as easily removed—an important feature to the user who rents his place of business.

Machine is completely protected with safety devices. Either part automatic or full automatic control is supplied as desired. It is unusually quiet in operation and can be placed in any desirable location.

Ask our nearest distributor for further details and prices.

Ask for a copy of our List of Users covering 48 pages of satisfied customers—also your copy of Ice and Frost.

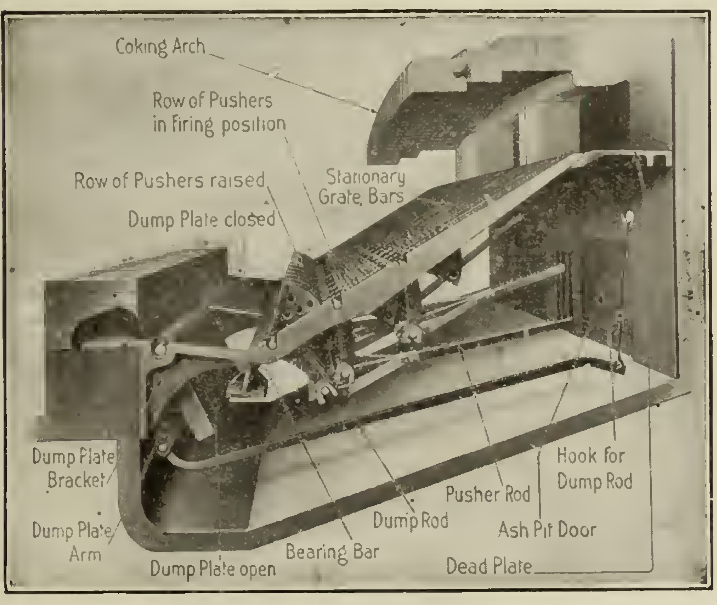
$1,946 Buys Your New Boiler

That is, if you want a 66″ x 16′ horizontal return tubular boiler, of 110 h.p., built for 125 lb. Interprovincial Code, complete with suspension harness, including columns — or $2,423 gets you a 72″ x 18′, 125 lb., 150 h.p. size, with other sizes (smaller and larger) in proportion. This is just to give you an idea of the moderate prices we make for first class Boilers, built of the highest grade materials, in the light of 35 years of practical experience. The increased power you get and the big savings in fuel effected by our boilers show you very handsome returns on your investment.



Big Savings are possible with the National Stoker

The special coking arch construction, possible only with the downward slope of our fire grates, is the most successful smoke consuming device you can use. Yet this arch is only one of several features that makes the National Hand Fired Stoker a wonderful fuel and labor saver. The downward sloping banks of grates operated by convenient Pusher Rods from the front of the furnace enable even "green" help to get perfect stoking results with almost any grade of fuel.

The National can be installed with your present Boilers. Send for illustrated booklet.

Automatic Valved Soot Blowers

Diamond "VALV-IN-HEAD"

As with previous mechanical soot blowers, the use of the Diamond "Valv-in-Head" effects a saving of 4 to 8 per cent. fuel and increases overall boiler efficiency.

As compared to previous mechanical soot blowers the Diamond "Valv-in-Head" also possesses the following distinct advantages:

1. LABOR FOR OPERATION—A saving of approximately 50 per cent.
2. STEAM FOR OPERATION—A saving of 50 to 60 per cent. or more.
3. PIPE, VALVES and FITTINGS—A saving of 50 to 66 per cent. in cost of pipe, valves and fittings.
4. MAINTENANCE—A reduction in annual charges of 25 to 50 per cent. or more. Practically complete elimination of condensate obtained.
5. EFFICIENCY—Greater cleanliness of boiler assured.

One of the most interesting publications in the power plant field is yours for the asking. It describes the savings effected by Diamond "Valv-in-Head" soot blowers in detail.

Ask for your copy of Bulletin 287.

Induced Draft System Makes Possible a Saving of Thousands of Dollars—Cheaper Coal is Burned

Ample power, though cheaper, poorer grades of coal are burned, and a most noticeable reduction in the cost of arch and boiler tube repairs are a certainty in power plants where Canadian Sirocco Induced Draft Systems are in operation.

Frequently the saving effected totals thousands of dollars each year.

Evidence of huge savings come to us from power plants in all sections of the country where Canadian Sirocco Induced Draft has replaced ordinary methods.

The following statement by the president of a large carton manufacturing company is typical:

> "When we could burn only the better grades of coal, fuel shortages frequently forced us to stop half our cardboard machines and lose 40 or 50 tons of production per day.
>
> "Eighteen months ago we installed your induced draft system and saved many thousands of dollars lost through such production tie-ups because it enabled us to get ample power with poorer, cheaper coal without any difficulty.
>
> "Formerly, even when we had the coal, our seven boilers (of 25,000 total horse-power) had to be forced very hard and 'bottled heat' resulted in arch repairs costing some $2,400 a year and tube repairs of $800 more.
>
> "Your System cut our arch repairs 75% and tube repairs 90%—thus saving us enough in repairs alone to pay its total operating cost, including interest, depreciation and power.
>
> "In 24 hour service, 6 days a week, for a year and a half it has given us great satisfaction and required no attention but lubrication.
>
> "With this equipment we get higher efficiency out of our coal, develop more power, save thousands in costly shutdowns and avoid $2,500 of troublesome arch and tube repairs."

Write to-day for our latest bulletin describing Canadian Sirocco mechanical draft equipment, both forced and induced.

On Great Engineering Projects

Following the hose and pipe lines from clanking rock drills, back perhaps to a shanty open to dust and dirt, we come to the throbbing air compressor.

The compressor rod packing forms an important item contributing toward successful and continuous operation. The intense dry heat of compression together with the abrasive action of grit and dust soon destroy a packing not designed for this trying service.

Garlock Style No. 222 combination packing, designed with a thorough understanding of compressor requirements, has given efficient and continuous service on compressor rods under all conditions.

DEPENDABLE POWER PLANT EQUIPMENT

Sectional Water Tube Boilers

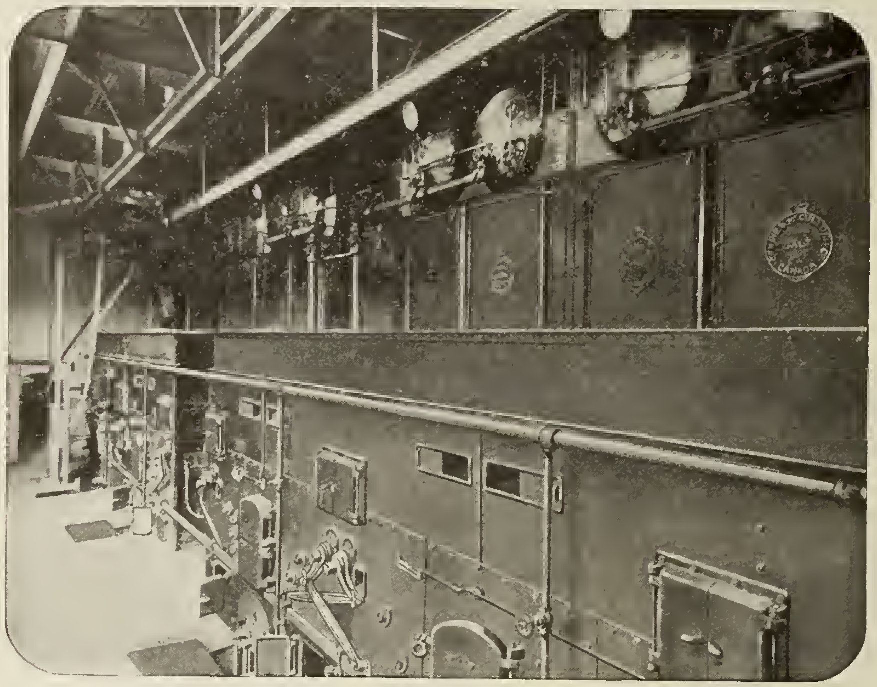

Illustration shows Boiler Room of The Toronto Carpet Company, equipped with 4 G. & McC. Double Drum Sectional Water Tube Boilers.

Superior in Design, Workmanship and Material

G. & McC. Sectional Water Tube Boilers provide more rapid circulation and increased steaming capacity. They can be forced without danger. Equipped with steam and water drum connecting nipples of increased size—lower tubes always supplied with water, and free passage is permitted for escaping steam.

Mr. Melvern F. Thomas, Consulting Engineer, in a letter dated May 23, 1922, has the following to say regarding the above plant:

"Three of the boilers are kept in service and during a part of the day are under heavy overload and we find them entirely satisfactory."

Principle of the Una-Flow Steam Engine

The Theoretical Advantage of a Una-Flow Compared With a Counter Flow Engine, Also the Features in the Design Upon Which Economy Depends, and its Increasing Popularity in Pumping and Rolling Mill Engines

L. T. RUTLEDGE[*]

AS A GENERAL rule, all new inventions are merely the applications of old principles, which may be very old indeed, so that the innovation, whatever it may be, carries with it nothing fundamentally new. The application of the principle, however, must be acknowledged to be original and new. In the case of the una-flow engine, which engine might be called a una-directional engine, the above remarks apply very fittingly.

As the name indicates, the energy is taken from the steam in the una-directional engine without causing the steam to return on its path. In the ordinary engine, with which all of us are quite familiar, the exhaust steam within the cylinder flows in a counter direction to the direction in which the expanding steam travels.

Becoming More Popular

The una-flow engine is at present coming into use in America. New engines are being installed and old counter-flow engines are being outfitted with new una-flow cylinders and steam valves. This new type of reciprocating engine has for some time occupied a conspicuous place in European manufacture, where it has been built in stationary, marine and locomotive types. It has become popular as a portable engine, a rolling mill engine and is much used for driving compressors, blowers, pumps, stamping machines and presses.

The first successful stationary una-flow engine was built at Brunn, Austria, by the Brunner Machinery and Manufacturing Company in accordance with the design of Professor Johann Stumpf, professor in the technical high school, Charlottenberg, Germany. The first una-flow locomotive was built and assembled in a Moscow railway shop for the Moscow Kazan Railway. Prof. Stumpf's pioneer una-flow engine proved highly satisfactory and showed a steam consumption equal to a first-class compound engine of the usual type.

The Idea Not New

Although the German engineers were the pioneers in putting the principle of the una-flow engine to a practical use, nevertheless it was an English engineer, J. L. Todd, who actually did the first research work on the application of the principle involved. Todd was granted the British patent No. 7301 in the year 1885. In this patent a very clear statement is set forth concerning the thermal conditions existing in an engine in which the inlet valves are located at the ends of the cylinder and the exhaust ports in the centre and controlled by the piston. Todd, however, in applying the principle made certain initial mistakes and failed to put the pure una-flow principle to practical use. Prof. Stumpf asserts in his writings on una-flow engines that his investigations have been carried on independently and without any knowledge of the nature of the work done by other investigators. It would appear that the present high degree of perfection in una-flow engines is due to the perseverance of Johann Stumpf.

Fig. 1 is a vertical longitudinal sectional sketch of the cylinder and adjacent parts of a double-acting una-flow steam engine. The sketch illustrates one of the first designs of Prof. Stumpf. The live steam is admitted through each cylinder head or cover of special design, the flow being controlled by valves. It will be noted that mechanically-operated exhaust valves are absent but instead of these there is a row of ports or slots at the middle section. This ring of exhaust ports makes it possible to have the area of the exhaust passage very much greater than is provided in the ordinary engine. The release and compression of the steam is controlled by the piston which is shown to be in length almost half that of the inner length of the cylinder. The piston is fitted with a set of three rings close to each end.

Exhaust Valves Not Essential

In the una-flow engine it is common practice to have the release take place after 90 per cent. of the stroke has been passed and compression begin after 10 per cent. of the return stroke has been completed. Thus compression extends over 90 per cent. of the stroke and thus it is possible for it to have a high value. Though the exhaust valves are shown to be absent yet there are una-flow engines equipped with exhaust valves where the specifications call for a variable release or compression.

Una-flow engines have their cylinder heads jacketed and for maximum efficiency the jacketing is extended along the cylinder to the point where cut-off takes place. The idea is to have the inlet as hot as possible and the exhaust as cold as possible. This is in accordance with a sound thermodynamic principle, first outlined by Carnot and illustrated in the famous Carnot's Cycle.

The una-flow cylinder consists essentially of two single-acting cylinders set end to end with a common exhaust opening and chamber. The heads remain hot on account of the jackets and yet the high temperature has no deleterious action on the cylinder and the piston. The exhaust belt is cold relatively speaking and remains cold, there being well-defined separation between the hot intake and the cold exhaust. Besides there is an extra advantage gained insomuch that the lowest cylinder temperature is secured where the piston velocity is the highest. As suggested by the sketch of Fig. 1, this cooling is facilitated by the dispensing with the steam jacket in the neighborhood of the exhaust ports.

---

[*] Assistant Professor of Kingston University.

The piston in this type of engine must, of necessity, be made quite long. It has, therefore, a large bearing surface and consequently a low intensity of bearing pressure. The cylinder itself is very simple in construction, being free from such subsidiary parts as are necessitated in, for example, a D-slide valve engine. This feature is of utmost importance, not only from a thermal point of view but also from a mechanical standpoint. When the steam chest is cast in one piece with the cylinder, the construction and moulder's core work is complicated, and very often considerable initial internal stresses are introduced. The cylinder heads in una-flow engines are much more complicated than in the counter-flow machines but since the pieces are never very large, the core work and moulding does not present any great difficulty. For perfect operation of a una-flow engine all that seems necessary is good workmanship and efficient lubrication. These, undoubtedly, are requisites in any engine of any design.

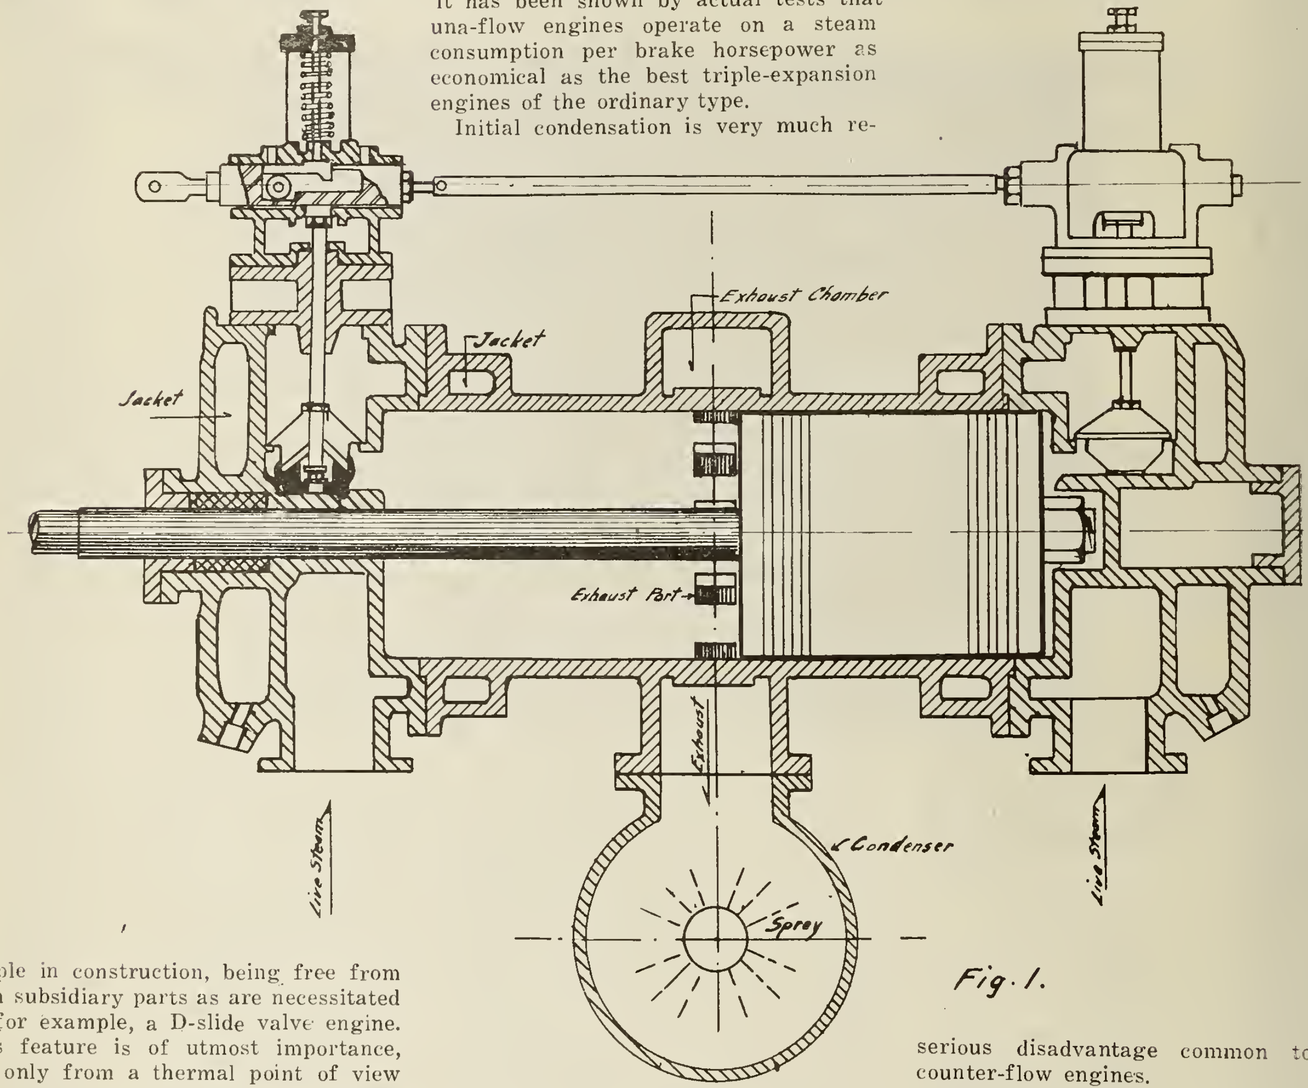

Fig. 1.

In the counter-flow engine the reversal of the steam during the exhausting period causes very considerable cooling of the clearance surfaces, steam ports and steam passages because of contact with the wet steam. This cooling results in initial condensation when the live steam comes into contact with the moisture deposited on the surfaces and entrained in the trapped steam. To offset this, the steam is superheated and several stages of expansion are used, as is the case where triple and quadruple engines are used. In una-flow engines the initial condensation is practically eliminated for reasons given below and it has been shown by actual tests that una-flow engines operate on a steam consumption per brake horsepower as economical as the best triple-expansion engines of the ordinary type.

Initial condensation is very much reduced in the una-flow engine by the unique position of the exhaust ports and by the system of steam jacketing employed. The wet steam after expansion, as suggested above, is exhausted out of the cylinder without coming into contact with the clearance spaces and passages through which the live steam has to pass, as illustrated in Fig. 2, which illustration is due to Prof. Stumpf. The wettest steam is in the layer nearest the piston and the wetness decreases back to the cylinder head. During the exhausting period almost all the entrained moisture passes out of the cylinder and any steam entrapped is the steam which was in contact with the surfaces heated by the steam jacket. The heat absorbed from the jacket is not lost in the exhaust but is retained during compression and is available for mechanical work on the next expansion stroke. Whereas in the ordinary counter-flow engine the exhaust steam must be in contact with the steam-jacketed surfaces since the steam jacket extends the whole length of the cylinder. The exhaust steam cannot do otherwise than absorb heat from the jacket and this heat is rejected to the condenser. Thus it is apparent that the una-flow engine tends to overcome this serious disadvantage common to all counter-flow engines.

Due to the absence of initial condensation, the expansion line for the una-flow engine is adiabatic or very nearly adiabatic and if superheated steam is used the compression line as well as the expansion line will be adiabatic. The adiabatic expansion gives an indicator card of greater area than a non-adiabatic expansion and it is the expansion line most desired. Only in high-speed engines of the counterflow type does the expansion approach the adiabatic, since the high speed does not allow sufficient time for any appreciable transfer of heat by conduction or radiation.

In the ordinary engine, due to the reversal of steam velocity, there is a considerable amount of eddying motion in the steam which results in the cooling action, whereas in the una-flow engine there is a comparative stillness among the steam molecules of one layer of steam relatively to the adjacent layer. This stillness is due, firstly, to the method of exhausting and, secondly, to the absence of a great amount of re-evaporation and, thirdly, to the combined heating action of the cover jackets and the high compression possible in the una-flow engines.

Correct Position of Condenser

Lastly, owing to the fact that a large exhaust area is possible, the exhaust pressure in the cylinder is practically equal to the condenser pressure, especially so if the design of the plant admits of the absence of a long exhaust main with sharp bends. A low condenser pressure is most effective when it is effective at the exhaust ports of the cylinder. In Fig. 1 the condenser is shown immediately beneath the cylinder which is the ideal position for it. This design may be effected by locating the condenser in the room below the engine room and directly below or nearly so.

It is claimed that una-flow engines have a minimum of leakage and this is a factor that contributes to economy. During the admission period the long piston with its double set of rings is between the boiler pressure and the exhaust. With good construction, leakage past the piston can be reduced to a minimum even with high pressures. The admission valves sustain the maximum pressure difference for a shorter period of exhaust. Much of the admission valve leakage in our ordinary counter-flow engines is caused by the violent fluctuations of temperature resulting in distortion of valves and seats. With the una-flow engines the inlet valves are kept at practically constant temperature. The valves used are generally poppet valves of special design and are supposed to remain tight under all conditions.

As a brief summary, the makers and advocates of una-flow engines state that by careful design and construction the seven principal losses common to other designs of reciprocating engines may be reduced to a minimum. These losses, some of which have not been discussed in the above explanation, may be listed as follows:

1. Losses due to surface condensation in the cylinder.
2. Losses due to leakage at valves and pistons.
3. Losses due to necessity of large clearance volumes.
4. Losses due to friction of auxiliary moving parts.
5. Losses due to heat radiation and conduction.
6. Losses due to inefficient expansion.
7. Losses due to wire-drawing of steam.

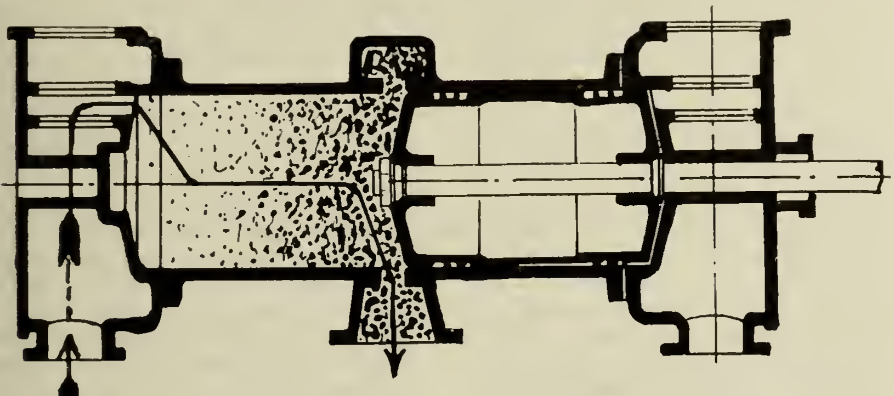

Fig. 2.

Better Results from Wire Rope. Too many accidental breaks occur from too little thorough knowledge of wire ropes, their strengths, and proper methods of fastening. There are six kinds of commercial wire rope, from iron having tensile strength of 60,000 lb. per sq. in. to improved plow steel with 220,000 to 280,000 lbs. per sq. in. Gives directions for telling various grades, and illustrated descriptions of various wedges and fastenings and methods of applying and using. E. O. Keator, Rock Products.

Gum Forming Constituents in Gasoline. Study of the various methods of evaporation and oxidation of cracked gasolines lead to the conclusion that gummy and resinous deposits are caused by oxidation and have no direct relation to unsaturation as determined by solubility in suphuric acid. A new and convenient method has been developed for determining these gums. They are probably polmerized aldehydes, which are formed from the oxidation of olefins, etc. Storage tests included in the paper confirm these conclusions. M. B. Cooke, Bureau of Mines, Reports of Investigations, No. 2394.

A BELT POORLY REPAIRED

Not long ago I was called to take a look at an oil-driven engine which the owner wished to dispose of because it "gave him too much belt trouble." The owner admitted that the engine itself was all right. He could find no fault with it as far as it running ability was concerned but, he said, "It breaks the belt as fast as I can fix it. I spend most of my time fixing the belt."

Of all the belts I have ever laid eyes on I never saw the equal to this one. I maintain that the said belt is the "most patched belt in the world." And I also maintain that it is the "most poorly patched belt in the world." The word "repaired" can hardly be used because it is too dignified a word in this case, and, besides, the belt wasn't repaired. It was just simply "patched." Originally, it was a double leather belt.

Whenever the belt would break the owner would simply take a piece of belting of the same width, lay it over the break, drive some rivets through, clinch the rivets, and let it go at that. No attempt was made to produce a smooth-fitting joint. No tapering down to a feather edge. No gluing. No squaring up with a square. The patch was simply laid on top, and, you might say, "nailed on."

Of course, the joint wouldn't hold long. Another splice would then be riveted on top of the first, the owner doubtless thinking that two splices should be twice as strong as one splice. And when that, again, would break, the owner "simply couldn't understand it." He decided that he would have to sell the engine and install a motor.

The entire belt was made up of splices in this manner, overlapping and underlapping one another until the average thickness was about equal to the thickness of three belts, one on top of the other. Never before has it been brought to my attention so forcibly that whenever a belt needs repairing it pays to do the job right in the first place. In this instance, if the first repair job had been properly done it is quite possible that up to the present time there would have been no need for a second repair job. The joint of a leather belt that is properly scarfed and cemented is just as strong as the solid leather belt itself. Leather-laced joints are of course never as strong as the solid leather, but if the owner had even laced his belt instead of riveting in this unworkmanlike manner, he probably would have had much less trouble. Wire-laced joints are stronger than leather-laced joints. They often have a joint efficiency of 85 to 90 per cent. A wire-laced joint could have been used as well as not, and the writer believes it would have held.

Owen Sound may install an asphalt plant in carrying out a proposed paving program. A movement is on foot looking to expenditure of $125,000 on harbor improvement.

Utilization of Waste Heat in Factories

The Author Has Succeeded in Condensing Information Lately Published Upon Heat-Saving Appliances, Used in England, America, France and Germany, and Adapted to Develop Greater Efficiency in Works and Factories

By JOHN B. C. KERSHAW

THE increased cost of most forms of solid and liquid fuel which has resulted from the war, in all countries, has rendered the subject of Waste-heat Utilization of exceptional interest and importance; for there are few manufactures in which some economies are not possible in this direction. In certain industries this waste of heat, and therefore of fuel, attains very large proportions. It is of course admitted that not all waste heat is economically recoverable, although scientifically this recovery may be possible. In the majority of cases, however, a very considerable percentage of the heat at present lost, with chimney-gases, exhaust-steam, and with other waste-products, especially in small works and factories, can be recovered at reasonable cost. Such recovery would promote not only the efficiency of the particular process, but also reduce the fuel cost of the product concerned.

Well-managed and up-to-date works and factories are no doubt already equipped with many of the devices and heat-saving appliances which will be described in the course of this article. The majority of smaller works and factories in this country (England), however, are still unprovided with them; and even when already installed, as in the larger works, they are not always operated so as to yield their highest efficiencies.

In order to show the magnitude of the heat losses that are occurring in many branches of industry, a few general figures may be given. The majority of power-plants in this country make use of steam for generation of the mechanical or electrical energy required to drive their machinery. The very best steam-power plant, however, can only yield the equivalent of one-sixth of the heat-value of the fuel at the shaft of the engine. The remaining five-sixths pass away with the exhaust-steam and chimney gases and in frictional or radiation losses. The losses that occur with the internal combustion engine are no less striking since 40 per cent. of the heat-value of the fuel is lost with the exhaust-gases and 28 per cent. with the cooling-water.

In the steel industry, nearly one-half of the heat actually delivered to the open-hearth furnaces is lost with the exit-gases; and in the coking industry, from one-quarter to one-third of the heat-value of the fuel is lost during the coking operation.

These figures and examples show the great importance and magnitude of the losses arising from the inherent defects of our methods for the conversion of the latent energy of coal or petrol into more useful forms of energy. These losses are proportionately as large when employing other forms of solid and liquid fuel.

The author in this article will attempt to condense into reasonable compass all the more valuable information which has been published lately on the subject of waste-heat utilization, and will describe the most efficient forms of heat-saving appliances that have been used in England, America, France and Germany. It is hoped that this summary of all the more recently published facts and figures will prove of considerable interest and value to those, who either as managers or engineers are responsible for the progressive development and efficiency of their works and factories.

Heat-Losses From Steam Boilers

As has already been stated, the best boiler and steam engine converts only 16 per cent. of the heat value of the fuel burned under the boiler into useful forms of energy, and 84 per cent. is wasted, chiefly in the chimney gases and in the exhaust steam.

Examining the losses in further detail, we find that the chief item in the boiler, is the heat carried away by the exit-gases, i. e., by the air used for combustion of the fuel. If oxygen gas should ever be produced sufficiently cheap and in adequate amounts to be employed for combustion purposes, this source of heat loss in furnaces and boilers might be greatly reduced; but so long as air is employed, a considerable loss of heat with the exit gases is unavoidable.

With regard to the calculation and checking of this loss, the measurement of large volumes of heated gas, or of the air flowing into the furnaces is, of course, a difficult matter. The CO_2 test of these gases has now been recognized as yielding the simplest and most reliable guide to the amount of excess air that is being employed for the combustion of the fuel. The following explanation of the reason may be quoted here, since many boiler-engineers do not understand clearly why this is the case:

Air contains in round numbers, 21 per cent. by volume of oxygen and 79 per cent. of nitrogen. When this oxygen is employed for burning solid carbon, it yields the same volume of carbon dioxide gas. If, therefore, the whole of the oxygen of the air could be used up in burning fuel on the grates of steam-boiler furnaces, and if this fuel contained nothing beyond carbon and ash, a maximum percentage of 21 per cent. CO_2 by volume in the waste gases would be attainable.

The hydrogen present varies considerably in different classes of solid fuel. In bituminous fuels it ranges, as a rule, from 3 to 6 per cent. By calculating the weight of oxygen required to burn the hydrogen present in the fuel, and by deducting from this, the oxygen contained in the fuel, one obtains the oxygen required from the air. Deducting the equivalent volume of this from 20.8,, we have the percentage by volume of oxygen available for combustion of the carbon. This figure for most bituminous coals is about 19.2 per cent., and this therefore represents the maximum percentage of CO_2 which could be obtained by perfect combustion, with the theoretical amount of air.

Now 12 lbs. of air are necessary theoretically to provide the oxygen required for the complete combustion of 1 lb. of ordinary fuel, and as this would yield, according to the above, a CO_2 test of 19.2 per cent., the calculation of the air excess for any other percentage of CO_2 is obtained, roughly, by dividing this into 19.2 and the lbs. of air by multiplying the result by 12. The formula $x = \frac{19.2}{y} \times 12$ is the algebraical expression of this method of arriving at the air excess, x representing the lbs. of air actually used per lb. of fuel burned, and y the average CO_2 test over a long period of time, for the exit-gases of the boiler.

As already pointed out, an air excess of from 150 to 200 per cent. is required to obtain perfect combustion of the carbon in solid lump fuel (dust fuel can be burned with a lower excess) in steam boilers. This signifies that for every lb. of coal burned in the furnace of the boiler, 18 to 24 lbs. of air must be passed through the boiler fires and flues. Adding the lb. of gaseous products obtained from the burning of the fuel, from 19 to 25 lbs. of gaseous matter are therefore passing up the chimney of the plant, per lb. of fuel burned.

The temperature of these exit-gases at the down-take of an ordinary tubular boiler is generally about 600 deg. F., and taking the Sp. heat of the exit gases as .24, the heat-losses in these two cases work out as follows:

(1) 19 × .24 × 600 = 2736 B. t. u.
(2) 24 × .24 × 600 = 3456 B. t. u.

Supposing, therefore, that a coal, testing 12,000 B. t. u. net, as fired, is being employed for the boilers, the percentage of loss in the first case is 22.6 per cent., and in the second 28.8 per cent., of the total heat-units contained in the fuel. The loss increases rapidly with every increase in the volume and temperature of the air passing through the furnaces. With 3.8 times the theoretical amount of air (corresponding to a 5 per cent. CO_2 test) and exit-gases at 600 deg. F., the percentage fuel loss rises to 40.88, and with exit-gases at 700 deg. F. to 48.46 or to nearly one half the heat value of the fuel, as charged into the furnace of the boiler.

These, of course, are extreme cases of bad management; but there are still too many small steam-power plants the engineers and firemen of which are running their boilers with a great excess of air in order to minimize the trouble from smoke. Five per cent. CO_2 tests would be found in many cases of these plants to-day, if such tests were being made. The average for the whole country would probably be 7 per cent., which is equivalent to 2.75 times the theoretical amount of air, and to fuel loss of about 33 per cent., when the exit-gases from the boiler escape at 650 deg. F. The heat-losses therefore which occur in the operation of steam-boilers entail the absolute waste of from twenty-five to fifty per cent. of the fuel used, unless heat-saving appliances are employed to reduce these losses to a minimum.

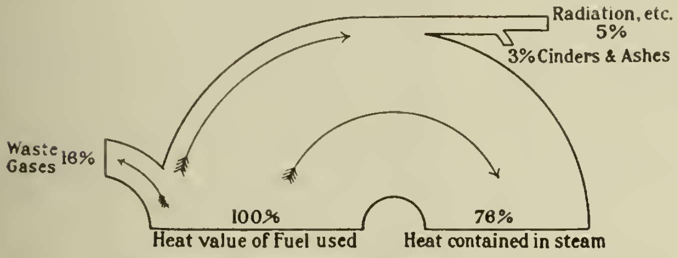

Fig. 1. Diagram of heat-losses in a well-managed boiler-plant.

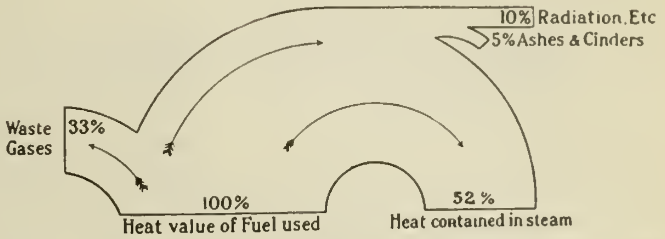

Fig. 2. Diagram of heat-losses in a badly-managed boiler-plant.

Where natural, i. e., chimney draft, is employed for working the boiler-plant, it is impossible to recover more than one-third or one-half of this waste-heat; for effective draft of a chimney depends upon the difference of temperature and consequently of weight between the column of heated gases inside the chimney and that of an equal column of the outside air. It is therefore not wise under these circumstances to reduce the temperature of the exit gases below 450 deg. F., for the lower the temperature of the exit gases, the poorer the draft. Where fan-draft has been installed, as in many of the more modern plants, it is possible to reduce the temperature of the exit gases to 265 deg. F., by the use of well-designed heat recovery apparatus. At this temperature, assuming that only the theoretical quantity of air is employed to burn the fuel, namely, 12 lbs. of air to 1 lb. of fuel, 13 lbs. of waste-gases are obtained, per lb. of fuel consumed, and the net B. t. u. lost would be 13 × .24 × 200 = 624, or only 4½ per cent. of the heat value of the fuel. This figure is, however, only of theoretical interest, for it is impossible to burn solid fuel completely under boilers with merely the theoretical amount of air admitted to the furnaces. It is rarely that the heat recovery plant is adequate to reduce the temperature of the escaping gases to 265 deg. F. Assuming, therefore, as air excess corresponding to 10 per cent CO_2 in the exit gases is employed, (equivalent to 192 per cent. of air excess), 23 lbs. of air will be required for each 1 lb. of fuel burned, and 24 lbs. of waste-gases will be obtained. Taking as before, the Sp. heat of these gases as .24, the heat units lost will be 24 × .24 × 400 = 2304 B. t. u., or 16 per cent. of the total heat value of the fuel.

This is the loss shown in Fig. 1, which has been drawn to illustrate in a diagrammatic form the heat-losses that occur in a well-managed boiler plant; whereas Fig. 2 illustrates, in a similar manner, the losses that are possible in a badly designed and badly managed installation.

It will be seen that the heat carried away by the waste-gases under ordinary working conditions may vary from 16 up to 33 per cent., and that the losses by radiation and with the ashes and cinders, will lie between 8 and 15 per cent. The total losses therefore range from 24 per cent. up to 48 per cent. of the heat-value of the fuel; and the steam ultimately obtained will represent only from 52 per cent. to 76 per cent. of the original heat-value of the fuel. These diagrams are well worth the careful study of chemical engineers in control of large works, for they show how important, and from the fuel-economy point of view, how urgent is the recovery of some proportion of this wasted heat.

Recovery of the Waste-Heat from Boiler Exit-Gases

The calculations and data given above show that even well-designed and well-managed boilers are unable to utilize more than 76 per cent. of the heat-value of the fuel, and that in a large number of cases the thermal efficiency of the boilers is not much above 52 per cent. The scope for waste-heat utilization in steam-power plants is therefore very considerable. Even when, by scientific management, the average thermal efficiency of all steam-boiler installations in the United States has been raised to 70 per cent., there will still be ample margin for the application of heat-recovering methods and apparatus.

Acording to Breckenridge about .255 million tons of the fuel raised annually in the U. S. A. are being consumed for steam-raising purposes, without including that consumed by the railroad companies. Since it is known from recent investigations of the efficiencies of land boiler-plants, that the larger number of these are being worked with efficiencies much below their maximum of 70 per cent., the fuel equivalent of this wasted-heat is calculated to be about 90,000,000 tons of coal per annum.

The question whether, in any particular case, it will pay to install heat-recovery apparatus depends more upon the temperature of the exit-gases than upon the size of the plant. In the majority of cases there is no doubt that the value of the fuel saved annually would more than cover the interest and amortization charges upon the economizers, or other forms of waste-heat apparatus installed. As a general rule, the gases which carry away this heat to the atmosphere leave the boilers at a temperature of from 600 to 700 deg. F. Now, taking the case of boilers burning 10 tons of fuel per day, or 50 tons per week, with the high average efficiency of 70 per cent., it is shown by Fig. 1 that 20 per cent. of the original heat-units of the

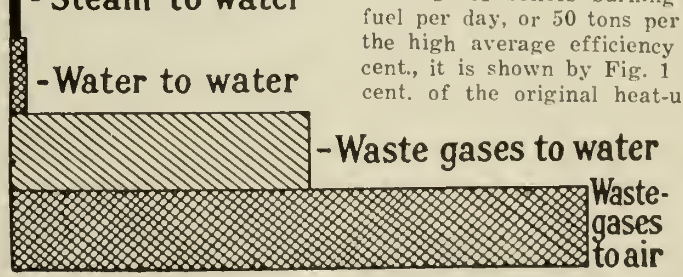

Fig. 3. Diagram of superficial area required for heat transfer from steam and hot air to water and air.

fuel will be present in the exit gases. Assuming that only one-half of these heat-units can be recovered, the weekly saving of fuel would be 5 tons, or 250 tons per annum; and at $6.00 per ton delivered at the bunkers, the annual cost of fuel saved would be $1,500. This sum would cover the amortization, interest, and upkeep charges upon a simple yet adequate heat-recovery apparatus.

Apart from this question of whether a heat-recovery plant pays, however, there is the question of the conservation of American fuel supplies; and manufacturers and engineers should be prepared to install heat recovery apparatus of this kind, simply because it enables them to obtain an equal heat effect, from a smaller consumption of fuel.

One may take it as proved, therefore, that in nearly all cases of steam-generation by the burning of solid fuel under boilers, some form of heat-recovery apparatus is called for, both on economic and national grounds.

Turning now to the consideration of the principles of heat recovery, as applied to the exit-gases of steam-boilers, it is at once evident that since air and water are the two chief requirements (apart from fuel), the preheating of these, before they enter the boiler, is the purpose for which the heat of the exit-gases can most usefully be applied. Engineers have in most cases in the past, chosen to apply this waste-heat of the exit-gases to the pre-heating of the feed-water by means of the apparatus known as "economizers," although there is no special reason why the term should be applied only to this particular water heating apparatus. The pre-heating of the water, rather than the air supply of the boilers has been adopted for three reasons.

In the first place, it is now generally recognized that a steam-boiler will only yield its highest thermal efficiency when fed with water at or near the boiling point for the particular steam-pressure under which the boiler is being operated. Feed-water heating has thus become accepted as a, sine qua non of efficient boiler management, and in all well-managed and well-equipped works it is customary to find not only the waste-heat of the exit-gases but also the heat of the exhaust-steam of the engines, applied to this purpose.

In the second place, it is also becoming more generally recognized that the gases dissolved in feed-water are the chief causes of the internal pitting and corrosion of boiler plates. Since pre-heating is one of the simplest and most effective methods of expelling these gases, it is very generally adopted on that account.

The third consideration is, that it is a more simple matter to transfer heat from a gas to water, than from a gas to air. The transference of heat from the exit-gases of the boiler to the feed-water, demands, therefore, a simpler form of apparatus than would be required for the transfer of this same amount of heat to the air. In connection with this subject of heat-transfer, the following figures and diagram have been published lately by Frenckel, a German engineer; and without in any way guaranteeing their accuracy, the author reproduces them here as interesting to all engineers engaged in the practical solution of problems of heat-recovery from water-gases.

The table appeared in the Zeits. Vereines Deutsch Ing., and is part of a lecture delivered before the Bochum Branch of the Verein. It shows the square meters of heating surface required to convey the same amount of heat, from and to, different heating agents.

	Heating Agent.		
	Steam	Hot Water	Air or hot gases
Product	sq. metres	sq metres	sq. metres
Boiling Water	1.0	2.3	93
Hot water	2.0	3.3	95
Air or hot gases	93.0	95.0	186

The figures of this table and diagram show that when heating water by aid of steam, for a stipulated transfer of heat, 2 sq. metres of heating surface are required; whereas when hot air or hot gases are employed for the same purpose, 95 sq. metres of surface are necessary. To transfer a similar amount of heat from hot gases to air, a heating surface of 186 sq. metres is required. It is for this reason that in the past waste-heat plants have been usually planned to recover the heat by steam, or hot-water, rather than in the form of hot-air, and that water economizers are found much more generally in connection with the utilization of the heat of chimney gases, than air-pre-heaters.

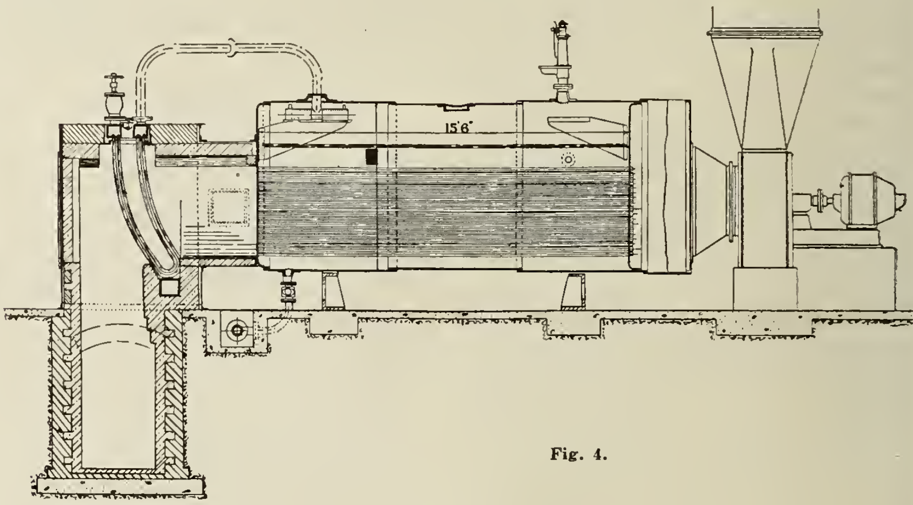

Fig. 4.

An economizer, in its simplest form, is simply an arrangement of cast iron pipes or tubes, 4 in. in diameter, and 8 to 10 feet in length, through which the feed-water is pumped on its path to the boiler. These tubes are placed in a special brick-work chamber behind the boilers, through which the exit-gases pass on their way to the chimney. Mechanical scrapers are used to keep the outsides of the tubes free from scale and soot. The flow of water through the economizer is on the counter-current principle, and theoretically the best results would be obtained with all the tubes connected in series. It is found impossible in practice, however, (owing to back-pressure) to operate more than two or three economizer tubes in series. Therefore the tubes in one economizer are all connected to the one water-supply box, and are worked in parallel, while the economizers themselves are sometimes operated in series.

As a general rule, only two sets of economizers are installed, and therefore the water has a passage of at most 20 feet through the heated tubes. This is sufficient, in the majority of cases, to increase its temperature up to 180 deg. F. The temperature drop of the exit-gases is about 300 deg. F. on an average, namely, from 650 deg. F. on the boiler-side of the economizer to 350 deg. F. on the chimney side. It is not, for the reasons already given, desirable to reduce the gases below this temperature, if natural or chimney draft is depended on.

The water supplied to the economizers should be raised to 90 or 100 deg. F. before entering the box that supplied the first series of tubes, otherwise sweating occurs, and external corrosion of the lower portion of the tubes results.

Considering first the theoretical aspect of the heat transfer in economizers, it is necessary to remember that the amount of heat transfered from hot gases, through an iron pipe to water, depends upon the temperature and velocity of the waste-gases; and that to obtain a high rate of heat-transmission, there must be either a high temperature-drop or a high velocity. In the former case the heat transmission is by conduction, in the latter case by convection. The researches of Kresenger and Barkley (see U. S. A. Bureau of Mines Bulletin No. 145) have proved that the rate of heat-transfer by conduction is practically constant per degree difference of temperature; whereas by convection it is nearly proportional to the velocity of the gases. Now in the economizer, both the temperature drop and the velocity of the gases are comparatively low, so the rate of heat-transfer is much lower than in the boiler.

In order to calculate roughly the amount of heating-surface required in an economizer, under stated conditions, in order to obtain specific results, the following formula may be used:

$$E = K\left(\frac{t_1 + t_2}{2}\right) - \left(\frac{t_3 + t_4}{2}\right)$$

in which E = the total heat units transmitted and recovered in British t. u. per sq. foot per hr. K = the heat-units transmitted per degree difference of temperature per sq. foot per hour. This value may fall from 4 to 1 if the tubes of the economizer are allowed to become covered with internal or external deposits.

t_1 = the temperature of the waste gases at the inlet to the economizer chamber.
t_2 = the temperature of the waste gases at the exit from the economizer chamber.
t_3 = the temperature of the feed-water at the inlet to the economizer tubes.
t_4 = the temperature of the feed-water at the exit from the economizer tubes.

Taking the case of a boiler which is evaporating a metric ton or 224 lbs. of water per hour, from water at an initial temperature of 50 deg. F. with exit-gases leaving the boiler at 750 deg. F. the above formula may be used to calculate the economizer heating-surface which would be required, in order to raise the whole of the feed-water to 194 deg. F. The economizer to give this result must recover per hour from the waste-gases, 2204 × (194 — 50) = 317,376 B. t. u. Now according to the equation, the amount of heat which can be recovered per sq. foot of economizer surface per hour, with fairly clean tubes, under the conditions given above is:

$$E = 2\left(\frac{608 + 311}{2}\right) - \left(\frac{50 + 194}{2}\right)$$

or 676 B. t. u.

$$\text{and } \frac{317.376}{676} = 468 \text{ sq. feet.}$$

An economizer tube, as a general rule, possesses 12½ sq. ft. of heating surface, and holds from 50 to 62 lbs. of water. In the above case, an economizer with 36 tubes would just suffice to provide the boiler with feed-water at the temperature required. In order to give satisfactory efficiency, economizers ought to possess sufficient capacity to hold fully one hour's feed to the boiler; and since the boiler in this case is required to evaporate 2204 lbs. of water per hour, an economizer of 36 tubes is requisite.

As already stated, when natural chimney draft is employed, the temperature to which the waste-gases can be reduced, is regulated by the needs of the chimney. For a boiler installation dependent for its draft upon a chimney only 80 ft. high, it is not wise to go below 550 deg. F., whereas with a chimney 135 ft. high the waste-gases can be reduced to 300 deg. F. without spoiling the draft.

In deciding upon the proper size of economizer for any plant it is sometimes customary to use the coal consumption as a basis of the calculation and to allow four tubes for each ton of coal consumed per week. Thus for a plant with a fuel consumption of 50 tons of coal per week, 22 tubes would be required. Another empirical rule, for calculating the size of water economizers, is, that their superficial heating surface should lie between one-third and one-fifth that of the boiler-plant to which they are accessory.

As regards the saving of fuel possible by heating the feed-water, assuming the initial temperature of 50 deg. F. and a final temperature of 180 deg. F., the saving will represent 11.23 per cent., and with a final temperature of 200 deg. F., over 13 per cent. The more wasteful in fact the boiler, the more useful becomes the economizer. It is a mistake, however, to purposely allow gases to leave the boiler with a high exit-temperature in order to obtain a greater effect from the economizers; for the more rapidly the heat generated from the fuel can be converted into the energy of steam, the higher the efficiency of the plant, since there is less opportunity for radiation and other losses. Further, the thermal efficiency of economizers owing to the small heat-drop and low velocity of the gases and to other causes, is low, and seldom rises above 25 per cent. It is, therefore, more conducive to economy to convert all the heat possible into steam in the boiler, and to use the economizer merely for trapping the heat units that cannot be utilized in steam-raising. Another disadvantage of economizers is, that if worked with natural draft they cannot be made adequate in size to extract all the heat-calories possible from the waste-gases; and that if worked with a fan and induced draft, the large amount of brickwork involved in their construction, increases greatly the risk of air-leakage, and reduces the efficiency of the whole installation. The following test of an economizer, under working conditions, shows the gain that may be expected to follow their use:

Heating surface of economizer	4300 sq. ft.
Coal consumed per hour	3035 lbs.
CO2 test of exit gases	12.26 %
Weight of gases passing to economizer per hour	108,827 lbs.
Weight of water passing through economizer per hour	33,877 lbs.
Temp. of water at inlet of economizer	91° F.
Temp. of water at exit of economizer	191° F.
B.t.u. absorbed per hour by water	3,387,700
Temp. of gases entering the economizer chamber	511° F.
Temp. of gases leaving the economizer chamber	232 F.
Mean temperature difference	230 F.
B.t.u. transmitted per sq. foot of economizer area per hour	787.8
B.t.u. transmitted per sq. foot per deg. F. per hour	3.42

Fig. 5. Diagram of Booth and Kershaw's system of waste heat recovery.

HEAT-BALANCE OF ECONOMIZER

For every lb. of fuel consumed in the boiler 6.72 lbs. of feed-water was raised through 100 deg. F. in temperature in the economizer	672 B.t.u.
Heat units contained in the exit-gases passing through the economizer chamber per hour	13,289,380
Heat units represented by gain in temperature of feed-water per hour	3,387,700
Economizer efficiency	24.5 %

Further calculations show that of the remaining heat-units, 38.79 per cent. was carried away by the waste-gases to the chimney, and 35.43 per cent. was lost by radiation, etc., from the economizer walls. The fuel economy resulting, in this particular case, from the use of the economizer was therefore 8.20 per cent.

Another test of an economizer carried out under strict conditions, yielded figures showing an efficiency of 26.16 per cent., and a value for R (the coefficient of the rate of heat-transfer) of 1.58, which is only half that obtained by the test given in detail above. In this case no doubt, the economizer-tubes were badly in need of a cleaning.

These figures prove that the rate of heat-transfer through economizer tubes, under actual conditions of work, is considerably lower than is usually assumed; and that more effective methods of cleaning them both on the exterior are necessary, if good results are to be obtained.

For these reasons the older method of cleaning by mechanically operated scrapers, is being discarded, since scrapers, unless very close-fitting, do not remove the whole of the soot, and more than half of the new installations of economizers in U. S. A. are reported to be having their tubes cleaned with a hand-lance. As regards the internal deposits of scale and sludge some important plants blow down once or twice a week, and also bore out the tubes once each year in order to keep the tube as free as possible from internal deposits; but the frequency of these operations must depend altogether upon the character of the water supply.

In many cases of economizers installed during the last few years, the induced-draft fans have been found of too small capacity to enable any overload to be carried by the plant. This brings one to consider the most serious drawback to economizers, namely, the large amount of brickwork which is involved in their construction, and the serious amount of air-leakage which occurs when, as is often the case, the installation is neglected and the brickwork is allowed to fall into disrepair. Whenever air leakage is suspected simultaneous tests of CO_2 contents of the waste-gases should be made, taking the gas-samples at the inlet and exit ends of the economizer chamber. The difference in CO_2 percentages will give some idea of the amount of air leakage and of the loss that is taking place in consequence of it. If serious leakage is occurring, the place can be detected by going round the brickwork with a lighted candle or burning taper, and noting where the draft draws the light into the cracks. The most likely places for cracks to occur, are in the side-walls, between the flue covers and tops of the economizer, around the bottom branch-pipes, and in the spaces between the top-boxes. The soot and sight-door joints are also places where air leakage may occur. Frequent pointing of the cracks may minimize the trouble; but the only real remedy is to enclose the economizer brickwork witht sheet iron, or with some other sheet material which will stand heat, and is impervious to air.

The large amount of heat (36 per cent. lost by radiation from the side-walls and tops of the economizers) is also a feature of economizer working which requiries attention; for there is no reason whatever why this loss should be permitted, or why economizers should not be encased in, or coated with, heat-insulating materials. A thousand heat-units when lost by radiation from the economizer walls, are just as much lost to the credit side of the heat-balance account, as if lost by radiation from the boilers. Could radiation losses from economizers be reduced by 10 per cent., that is to 25 per cent. of the heat passing through them, their efficiency could be raised to a much more satisfactory figure, than that given in the two tests quoted above.

There is no reason also, when fan-draft has been installed, why the exit gases from an economizer should be allowed to escape to the chimney, still carrying 40 per cent. of the original heat units contained in them when issuing from the boiler. It may not be practicable, for the reasons already given, to cool these gases to atmospheric temperature in the economizers themselves, but some other method of saving these heat-units ought to be adopted.

Many years ago, the writer of this article, in collaboration with the late Mr. W. H. Booth,* suggested that the heat contained in the exit-gases from economizers might be utilized for pre-heating the air-supply to the boilers, and the following extract from the I. E. E. paper in which this plan was advocated, may be given here:

"The ideal system would be to reduce the exit flue-gases to atmospheric temperature, by means of economizers, air-heaters and preliminary feed-water heaters—chimney-draft being dispensed with, and the draft produced by fans. The preliminary feed-water heaters would be placed last in such a system, and the whole of the remaining heat would be removed from the exit-gases by spraying the water through them, or by use of a tower filled with tiles or flints.

"Little or no unconsumed carbon would be produced under the conditions obtaining with a very high temperature in the combustion chamber of the boiler furnaces, and the sulphur dioxide and CO_2 absorbed by the feed-water would be neutralized in the water-softening operation. It must be remembered here that the sulphur would finally appear in the boiler as sodium sulphate; but the authors suggest that it (the sulphur) might be recovered in some way, and made a source of revenue to the feed-water purification plant. The air-heater would be of the type used in the regenerative gas-furnace—lengthened contact with a considerable surface of heated brickwork being necessary to heat air, which is a poor conductor of heat, and demands time for its temperature to be raised."

Although this plan of recovering all the heat-units from the waste-gases of boilers has not yet been operated upon an industrial scale, the writer is convinced that it (or some modification of it will be adopted) when the need for practising fuel-economy becomes more and more pressing, in this and other manufacturing countries. The only alteration the author has to make in the original suggestion is, that the air-heaters should be planned on the lines described in the next section of this article; since what is known as the regenerative system of air-heating (as applied in the Siemens gas-heated glass and open-hearth furnaces) demands very extensive chequered brickwork chambers, with complicated flue systems and change-over dampers; whereas. what is known as the "recuperative" type of air heater, is of fairly simple design.

If economizer-working does not develop in this direction, it is probable that it will give place entirely to a system and type of water-heating apparatus, planned on the lines of the Kirke waste-heat boiler.

Owing to the much higher pressures now being used for steam-engines and for steam-turbines, the use of cast-iron tubes for economizers is no longer quite safe. Owing to their design and large number of tubes, economizers provided with steel tubes are very costly, although they have been adapted in a few cases in U. S. A. The Kirke waste-heat boiler, of course, demandse a powerful fan-draft, in order to overcome the resistance offered by the length and narrowness of the tubes, through which the gases are drawn. On the other hand there is no brickwork involved in its construction, and therefore no air-leakage can occur. The heat transfer to the water in the boiler in fact can be made so efficient, that the temperature of the escaping gases can be reduced to within 80 deg. F. of that of the water contained in the boiler. It may be admitted that a Kirke waste-heat boiler is more costly to install than an economizer, but its heat-efficiency is far higher; and now that higher temperatures and pressures are being employed for boiler working, the demand for heat recovery apparatus that is both safe aand efficient is certain to increase.

Up to the present time, the Kirke waste-heat boiler has been employed chiefly for recovery of the heat from the waste-gases of metallurgical and other furnaces; but the writer expects to see its sphere of application and usefullness widened, as the need for higher and yet higher thermal efficiencies in steam boiler practice grows more urgent and insistent.

A scheme of hydro-electrical development on the east branch of Bear River, Nova Scotia, at a probable cost of 11,150,000 dollars, which would supply the north shore of Nova Scotia from Yarmouth to Middleton, was recently outlined by Mr. K. H. Smith, chief engineer of the Nova Scotia Water Power Commission. The work had, he said, so far advanced that, within a very short time the Commission would be prepared to suggest a definite contract for the approval of the town. Distributing stations under the plan would be at Middleton, Bridgetown, Annapolis, Bear River, Digby, Weymouth, Port Maitland and Yarmouth.

Experiments carried out in America on the treatment of carbon monoxide asphyxia have shown, according to the Gas Journal, that when breathing oxygen the rate of elimination of carbon monoxide is somewhat more rapid than when the subject breathes merely air, but that the elimination is enormously accelerated when the inhalation consists of oxygen, plus carbon dioxide. A blood concentration of carbon monoxide of 40 to 50 per cent. saturation (a dangerous amount) was reduced to 10 or 12 per cent. (a quite harmless amount) in half an hour.

Canada has sufficient coal to last 30,000 years, according to Dr. Charles Camsell, Deputy Minister of Mines.

Radium has been discovered on the Petawawa River near Pembroke, Ontario, according to a report from Toronto.

With 55 thousand million tons of lignite in the southern part of Saskatchewan, the Provincial Government is not going to give up the experiments now being conducted by the Lignite Utilisation Board at Beinfait until it is proved

(Continued on page 30)

Safe Practice in Handling Acetylene Generators

Best Housing Methods Under Different Conditions—Fire Hazard Requires Special Attention—Natural and Artificial Lighting of Buildings—Pressure in Pipe Line Important

IT IS ALWAYS desirable to have two workmen trained to properly operate the acetylene generator. If you only have one man in your employ who knows how to operate the generator and he should be sick or absent from other cause, you are liable to permit a man who knows absolutely nothing about the operation of the generator to attend to it, and possibly with serious results, and the chances are that your foreman or ever you, yourself, have not enough knowledge about the generator to tell an unskilled man how to operate it or to judge whether he is operating it properly.

Recharging Generators

In the recharging of acetylene generators it is most important to follow the orders and instructions for consecutive operations as laid down by the manufacturer. Manufacturers of acetylene generators have endeavored, as far as seems humanly possible, to make their generators fool-proof, but the idea has never been quite accomplished. It is most important to remember when an acetylene generator is recharging that the generating chamber which contains the water and spent carbide is first of all drained or flushed out and again filled with water before any attempt is made to open or fill the hopper or container with carbide.

Supposing you have drained all the water from the generating or water chamber and that you then before refilling it with water, fill your carbide hopper, there is just the possibility that a piece of carbide may drop down through the feeding mechanism into the empty generating chamber. You must remember that the bottom of this generating chamber will probably have a coating of moist lime sludge. The moisture will attack the carbide and start to decompose. There is, however, not sufficient water to cause the decomposition to take place rapidly and, as a result, the decomposing carbide may heat up and reach a temperature where it is possible for it to ignite a mixture of acetylene and air. Remember if the carbide hopper were opened up before the generating chamber was filled with water, it would be possible for some air to have got into it.

Special attention should always be given to making sure that the hydraulic seals and backflash devices at the discharge of the generator are properly filled with water and are in proper working order. The pressure relief valves, which are commonly employed on what is known as the medium pressure type of generator, should be tested periodically in order to see that they are working freely and release at the proper pressure.

If any repairs have to be made to an acetylene generator, the whole machine should be thoroughly flooded with water to make sure that all gas has been expelled. This may seem very elementary advice, but history seems to warrant it being given as often as possible, and notwithstanding the fact that this advice is given on every possible occasion, workmen will sometimes occasionally open up an acetylene generator to make some minor repair or adjustment and then, without making sure that all gas has been expelled, start to use some metal tool and create the spark necessary to cause trouble.

In these cases where the shops are piped for oxygen supply and the oxygen is supplied from a number of cylinders manifolded together, it will probably be arranged for the same man who looks after your acetylene generator to look after the oxygen manifold and replace the exhausted cylinders with full ones when necessary. It is essential that the workman looking after this work be very carefully instructed in the matter of handling the cylinders with his hands free of grease or oil. When the empty cylinders are disconnected from the manifold and put on one side, the full ones that are to be attached should all have their valves cracked, that is to say, they should be opened very slightly for a moment to blow out any dirt or foreign matter that may have accumulated in the valve orifices during transport or storage. The cylinders should then be connected up in turn through flexible connections to the manifold and the valve on one cylinder opened up, care being taken to open the valve slowly so as not to throw a pressure of 2,000 pounds suddenly on the system. With the valve of one cylinder opened up, the manifold and all connections will contain oxygen at 2,000 pounds per sq. in.

Search for Leaks

A careful search should then be made for leaks, which will be detected by a hissing sound. Connections where leaks occur should be tightened up immediately. After the operator has made sure there are no leaks in the manifolding system, the rest of the cylinders connected to the manifold can be opened up. It should be appreciated that it is necessary to open the valves on oxygen cylinders fully. If any cylinders are found that leak around the valve stem they should be disconnected and returned to the manufacturer.

Under no circumstances whatever should workmen be permitted to attempt to make any repair to the valves and valve fittings on an oxygen cylinder. All oxygen cylinders are fitted with valves having right-handed connections. Unfortunately, certain combustible gases are stored in cylinders of similar size and appearance to oxygen cylinders. Such cylinders should, in the cause of safety, be equipped with left-handed valves, but

The cutting operator working on the outside of the casting cannot see the line of cut. The man in the picture is his helper and is guiding the cut with signals.

As recommended by the National Safety Council.

there are no laws which make it possible to enforce such a safety measure, and I regret to say that there have been one or two isolated instances where a cylinder of combustible gas has been connected up to an oxygen manifold along with oxygen cylinders and with, of course, disastrous results.

These occasions, however, have been so very rare that there is really nothing much to worry about, and even if every combustible gas cylinder were equipped with left-handed valves we would still have the man who might occasionally, by some means or other, connect a right-hand connection to a left-hand connector. As a matter of fact, cases are known where an operator endeavored to connect up a connection from an oxygen manifold to a cylinder of combustible gas, and he found he was unable to make a proper connection because the thread on the valve of the combustible gas cylinder was left-handed. This, however, did not thwart the determined worker and he went into the machine shop and got them to make up an adaptor for him so that he could make the connection. Now when instances of this sort do occur it is very clear that the workman delegated to look after cylinders, generators, etc., has not been properly instructed and cautioned.

Operation of Welding Units

It is quite needless to talk about the operation of the actual welding units, that is, the blowpipe, gas regulators, hose, and the installations using individual oxygen and acetylene cylinders where they are employed. Every manufacturer of apparatus puts out detailed instructions on how the various items of equipment are to be connected up and operated, and if users would follow these instructions, few, if any, accidents would occur. If, for some reason or other, oxygen or acetylene regulators which are employed for adjusting the pressure of the gas for delivery to the blowpipe become disarranged, do not permit your workmen to attempt to repair these themselves. Large establishments can, of course, have a department where welding equipment can be periodically overhauled, repaired and tested, and can employ in that department a man who is properly and thoroughly skilled in his work; but in the case of smaller establishments, it is advisable for defective apparatus to be returned to its manufacturer when overhaul or repair is necessary.

Testing Working Pressure

It is very important to periodically test the working pressure gauges on the regulators. These are the pressure gauges that indicate the delivery pressure of the gas from the regulator. As previously mentioned, acetylene should never be used in a blowpipe, or in a hose or piping system at pressure over 15 pounds per sq. in., and it is on this account that we emphasize the importance of making sure that the working pressure gauges, particularly those on the acetylene supply, are periodically tested to see that they register correctly. You hear occasionally of accidents where the hose supplying the gas to the blowpipes has burst. In nearly every case this can be traced down to the fact that acetylene was being supplied to the hose at a pressure in excess of 15 pounds per sq. in., either intentionally or because the working pressure gauge on the regulator did not record properly, with the result that a backfire in the blowpipe propagated through the blowpipe to the hose. Now appreciate that the backfire would not matter at all if the pressure in the hose was not above 15 pounds per sq. in. The acetylene would not even burn. But when the pressure is over 15 pounds to the sq. in. the acetylene may readily decompose and cause the hose to be ruptured, and probably disarrange the functioning of the regulator attached to the gas cylinder.

Proportions of Hose

Guard against using long lengths of hose of too small a diameter. Quite a number of blowpipes only function properly when the acetylene is delivered to the inlet to the blowpipe at pressure somewhere between 10 and 12 pounds to the sq. in. Therefore care must be taken to see that the diameter of the hose is large enough in proportion to the length to be employed to insure that the drop in pressure between the outlet of the regulator and the inlet of the blowpipe is not more than a pound or so.

It is probably advisable to say a few words about the acetylene cylinders. Some of you may not appreciate the fact that an acetylene cylinder is not merely an empty shell containing compressed gas the same as an oxygen cylinder. The interior of an acetylene cylinder is completely filled with a porous material such as asbestos, or a concrete made up of charcoal instead of crushed stone. This porous mass has a porosity of about 75 to 80%, and is being employed for the following reason:

It is found that if acetylene is compressed into a porous substance, and where the porosity does not exceed 80%, and acetylene cannot be exploded or ignition propagated when the pressure is over 15 pounds per square inch, as it could be if the cylinder contained no porous mass. Therefore, a cylinder properly constructed and containing the proper porous mass can be safely used for the storage of acetylene at over 15 pounds pressure per square inch. Cylinders commercially used today, in addition to containing the porous mass, also have in them a solvent, which will dissolve many times its own volume in acetylene, thus making it possible to store in the cylinders large quantities of gas at comparatively low pressure. A charged cylinder of compressed acetylene contains practically no free gas. All the gas that is in the cylinder is in solution in the liquid solvent, which liquid solvent is in turn absorbed in the porous mass in the same manner that a sponge absorbs water. When the valve of the cylinder is opened and pressure released, the acetylene gas comes off from the solvent in the same manner that CO_2 bubbles up through the water in a seltzer water syphon when the valve is opened. Acetylene cylinders should always be stored and used standing upright.

Safety Fusible Plugs

As mentioned previously, the safety devices in acetylene cylinders consist of fusible plugs which melt at a temperature of 212° F. It will therefore be seen that care must be taken not to let any flame come in contact with the fusible plugs. Otherwise they will melt instantly and release the full charge of gas in the cylinder.

Make a point of insisting that all welding operators wear suitable goggles. When securing suitable goggles it is advisable to have them comply with the specifications for goggles of the National Head, Eye and Ear Code for acetylene workers. Welders employed on heavy work should be supplied with fireproof gauntlets and aprons as a protection against radiated heat, and it is considered advisable where welding is being performed in the interior of some structures to insist that all outer clothing be fireproof.

Get The Safety Habit

It is sincerely hoped that some of the recommendations may help to steer you clear of accidents which need not occur, but don't forget that safety practice does not end with proper operation of your welding equipment. Welding must only be used for work where welding can be considered good and safe practice for construction or repair. Some users become over-enthusiastic and attempt to employ welding on certain work where it should never be attempted and consequently fall down badly, with the result that it tends to give welding a bad name and creates a feeling of insecurity about the process in the minds of those who are considering its use.

UTILIZATION IN WASTE

(Continued from page 28)

beyond all doubt that briquettes cannot be made from the fuel. The Saskatchewan Government has contributed almost a quarter of a million dollars as the Province's share in this experimental work.

A factory is being put up by the Canadian Salt Company, Limited, at Windsor, for the manufacture of liquid chlorine. It will have a capacity of 10 tons per day, and will be producing shortly. This is the first plant of its kind to be erected in Canada.

Engineers Discuss Boiler Problems

Annual Meeting of Mechanical Engineers in New York Has Many Features of Interest—Animated Discussion on Power Equipment, Management, Test Procedure and Make-up of Codes

THE FORTY-THIRD annual meeting of the American Society of Mechanical Engineers was held in New York on Dec. 4 to 7. With an attendance of more than 1,600, it was one of the most successful conventions in the history of the society. The outstanding feature was the animated discussion and interest in problems associated with the use of higher steam pressures and temperatures in power-plant work and in connection with the use of stokers and coal and ash-handling equipment for central-station plants. Another prominent feature of the convention was the notable address of the retiring president, Dexter S. Kimball, dean of the Engineering College of Cornell University, on the place of the engineer in modern industrial civilization. President Kimball has been preaching the gospel of social service and the possibilities of the engineer in the political field during the past year and has aroused a great deal of interest throughout the country on this subject.

Ash-Handling Methods

Ash handling was the subject of discussion at one entire session, the feature of which was a paper presented by John Hunter, chief engineer of the Union Electric Light & Power Company, St. Louis, and Alfred Cotton, chief of the research department of the Heine Boiler Company. The paper embraced a very extensive and complete discussion of the methods of removing ashes from basement boiler rooms, the design, construction and capacity of hopper ash pits, systems of mechanical conveyance and elevation, fluid and gas conveyance, and the final disposal of ash. Sufficient description and illustration of all successful methods of handling ash were given to enable those interested in the subject to lay out or criticize intelligently almost any installation with which they may be confronted.

Several engineers discussed the general problem of ash handling, attention being centred on (a) the logical fields for different types of ash-handling equipment, (b) the place and limitations of gas and fluid conveyors, (c) the size of ash pits and storage base, and (d) quenching of ashes.

Unless carefully designed and laid out, the steam-jet ash conveyor is very uneconomical in steam consumption, Eugene Hahn declared. The design of the nozzles is extremely important, and fittings, especially elbows, should be provided which will strongly resist abrasion and can be readily replaced.

The serious effect of small-size ash pits on stoker maintenance was emphasized by T. A. Marsh, who illustrated both good and faulty designs. He strongly advocated much larger ash pits than are ordinarily employed. Commenting on gas-type ash conveyors he contended that they are not suitable where considerable clinker has to be transported. Worn nozzles were pointed to as the chief cause of excessive maintenance in gas-type conveyors.

F. D. Allen maintained that most methods of quenching ashes are inadequate and advocated a system in which water headers run along the outside of the ash hoppers and connect with easily accessible spray nozzles that discharge water over the surface of the ashes. The principal advantages claimed for this system were the more uniform cooling of the ashes and the greater reliability and flexibility of operation. With tight-fitting hopper gates and drains for water discharged into the hoppers the basement floor can be kept dry, and a water seal can be maintained which will increase the economy of operation of the furnace. The speaker also referred to an installation at Durham, N. C., where carbon is being recovered from ash at a cost of 40 cents to 60 cents per ton.

More attention must be given to the working conditions under which boiler refuse has to be handled in designing ash-disposal systems, R. H. Beaumont said. Furthermore, the systems must be laid out in such a way that various means of removal from the plant can be utilized in emergencies.

Bottom-Dump Hoppers

Of all the systems considered by Mr. Hunter in his paper, N. E. Funk favored the bottom-dump ash hopper with railway or industrial cars for removing ashes. He maintained that this system is most easily operated and maintained, is flexible in operation and can be replaced by some emergency expedient when necessary. No more headroom is required than for other systems, he contended. Ample ash storage is imperative because emergencies will arise when the largest storage will be insufficient. Referring to water-sealed ash pits, he declared that they are somewhat untidy and are amenable to operation only with overhead cranes or grab buckets operated by a locomotive crane. The carrier-ring system of coal and ash handling is objectionable because it may discharge ashes into coal bunkers; the cross-bar conveyor, even when duplicate conveyors are employed, may shut down all the boilers in a row, and the vacuum ash tank is liable to blow up because of the generation of gas. In one 60,000-kw. plant using coal containing 15 per cent. ash and operating at 70 per cent. load factor it has been possible to handle all the ashes with two storage-battery locomotives, industrial cars and two men, Mr. Funk declared.

N. W. Elmer pointed out that disposal of ash will be a serious problem for all to consider if powdered fuel becomes more extensively used.

In congested sections it is becoming a very big problem how to dispose of ashes, I. E. Moultrop declared. In such places big ash pits are imperative. Furthermore, the ash-handling equipment must be simple and should not break down easily. The ash hoppers should be high enough to permit railway cars trucks or industrial cars to be run under them to remove the ashes. In emergencies the ashes can be dumped on this floor and removed later.

At Cleveland industrial cars and a skip hoist are employed to handle ashes, asserted T. Mainz. In emergencies the ashes are dumped on the floor. The speaker warned against cutting down the size of ash pits and storage space.

Explaining his reason for adopting submerged ash pits, G. G. Bell said that they prevent the emission of carbon monoxide, corrosive gases and flames and simplify the problem of ventilating the ash room. Furthermore, they cost only two-thirds what other ash pits would have cost. At the Windsor plant ten days' storage is provided in the submerged ash pits, the contents being removed by a crane, conveyor and aerial tramway. The aerial tramway which has recently been installed will take care of conditions for some years to come by filling in ravines around the station. Ashes can be handled with this tramway at a cost of 25 cents per ton, and this cost may be reduced to 12 to 15 cents.

In a written communication from E. H. Tenney it was pointed out that freezing of gates on overhead ash hoppers during cold weather can be prevented by steam lines.

In closing the discussion, Mr. Hunter pointed out that operating engineers are anxious to secure the largest ash pits possible, but monetary conditions sometimes stand in the way. He questioned the economy of recovering carbon from ash in most plants. Despite the comments on gas and fluid ash conveyors, he contended that they had a definite field and must have consideration for the reasons previously outlined; besides, they provide considerable storage. In emergencies they can be unloaded by locomotive cranes if sufficient headroom is available. Referring to the disposal of ashes in powdered-fuel plants, he pointed out that John Anderson of Milwaukee has claimed that he has been able to remove 50 to 100 per cent. of the ashes by washing the flue gases. He insisted that more consideration must be given to the problem of handling ashes in small plants.

Material-Handling Equipment

A report was submitted by the committe delegates to develop formulas for calculating the investment justified in material-handling equipment, the yearly cost of maintenance and the yearly profits. Mr. Hunt pointed out that the formulas are very simple to use but cannot be presented without considerable explanation.

Stoker Symposium Arouses Interest

A profitable session was held under the direction of the fuels division, with Prof. L. T. Breckenridge in the chair. A symposium on stokers was presented in the shape of four phases, which outlined in detail the field, the operating possibilities, the installation methods and the development of the modern stokers. T. A. Marsh discussed the development and use of the modern chain-grate stoker and showed how greater boiler capacity can be obtained by increasing grate size or by increasing the draft. He gave in detail the operating possibilities of the modern chain-grate stoker for power purposes, including a table of results obtained by a number of stations equipped with these chain grates.

In discussing the overfeed-type stoker, G. I. Bouton stated that apparently this type has reached a limit in a stoker having a projected grate area of 100 sq. ft. to 110 sq. ft. in a single unit capable of burning sufficient coal under forced draft to develop about 2,000 boiler-horsepower at the maximum. Mr. Bouton discussed the development and present success in method of operation of the front and side-feed types of the inclined overfeed stoker, and gave illustrations of the settings. The effect of the content of ash in determining the fusion temperature was also discussed.

H. F. Lawrence labeled his paper "The Design and Operation of Underfeed Stokers" and described briefly the distinctive features of the single and multiple retort types of underfeed stokers, giving illustrations of a number of each type as well as particulars regarding their operation and results that have been obtained. The author accented the advisability of giving attention to the secondary feed system and pointed out the types of coal to which this type of stoker is best adapted. He also gave some very good curves and data showing the best types of fans to be used in stokers and a table of settings for the boilers.

The chronological history of stoker development to the present day was the subject of a paper by A. H. Blackburn.

These papers were discussed as a whole by many members, and much valuable information was obtained from those who have had experience with the several types. The consensus of opinion was to the effect that the chain-grate stoker was best adapted for burning high-ash Western coal. In connection with the operation of the chain-grate stokers, however, T. L. Mainz pointed out that among points to be watched is the amount of carbon in the ash and trouble with the seal at the end of the stoker. He said that the best results could be obtained by having a uniform size of coal sent to the grate and that this was a part of the function of the coal-handling system. Another point he mentioned was that the boiler-room dirt must be eliminated when using forced draft under the chain-grate stoker. Further discussion brought out the fact that several types of the modern stoker had solved these problems successfully.

H. C. Heaton of Sargent & Mundy pointed to results obtained by operating chain-grate stokers and said that one of the great features was to insure the proper spreading of the coal and that his experience indicated the movable spout as the most successful means of securing proper spreading.

In a general discussion W. N. Polakov brought out the fact that in many cases the installation of good types of stokers was in itself no guarantee of efficient operation. The human element must be considered and the personnel trained if good results are to be obtained. Mr. Roney also accented the necessity for a skilled personnel, and D. M. Meyers pointed out that, in engineering terms, a stoker's effiicency was the product of the mechanical efficiency by the human efficiency. He asked questions about the formation of clinkers on the underfeed type of stokers and the value of automatic control equipment and the ratio of combustion space to the capacity of a boiler, and also asked what possibilities there were of introducing stokers into marine practice.

Other speakers brought up the point that with modern conditions for obtaining coal it is a necessity to have a stoker that will operate under a wide variation of fuel conditions and, if at present there are seventy-five fuels and five stokers, the ideal thing would be to have one stoker that could burn any of the seventy-five fuels. Discussion brought out the fact that this ideal could not be reached at present, but that several types of stokers could burn a wide variety of fuels with success and efficiency. Another point brought up in this discussion was that the coal-handling equipment is a part of the stoker problem and that the furnace setting in particular is very important to insure proper upkeep of furnace refractory material and the arrangement of the material in the furnace. Devices for obtaining the best operation for a given type of stoker and for getting rid of ash and clinker were discussed. O. P. Hood mentioned, incidentally, that a committee was at work to try to standardize engineering details in an anti-smoke ordinance.

Question the Use of Automatic Equipment

One of the most interesting points in the discussion was regarding the necessity and advantage of using automatic stoker control equipment. The points brought out were to the effect that it was almost a necessity to afford the boiler-room employees proper training facilities, meters and instruments. Automatic equipment, it was pointed out, is a safeguard in regard to pressure maintenance. In many ways it is far from ideal, but much may be expected as it is developed. The parallel operation of boilers and fans with control based only on steam pressure was mentioned as decidedly a makeshift proposition at the present time, but several members maintained that by using a certain number of the boilers to maintain pressure with manual control of firing maintenance on the remainder of the boilers a good combination for obtaining reliable and efficient operation would be gained.

Industrial Education and Training

One session of the meeting was devoted to the education and training of men for the industries. This was taken up from the standpoint of the correspondence school, extension course and apprentice course in industries, and very valuable material along these lines was compiled and presented by a committee. The statistical information afforded an indication of the great increase in training men for the industries.

Baffling the Boilers

Results of extensive tests on large type W Stirling boilers at Deroit to determine the effects of different baffle arrangements, grades of coal, banking methods, intervals between blowing of flues and methods of operating during low-load periods were presented by P. W. Thompson. As a result of these tests the boilers have been rebaffled with considerable improvement in efficiency and degree of superheat, and the Babcock & Wilcox Company has developed a new design of this type of boiler. The baffling arrangement selected exposed two layers of tubes to the radiant heat of the furnace and allowed the gases to cross the inner bank of tubes at the top, pass the superheaters and then return along the outer bank of tubes to the stack. With this arrangement an average increase of 50 deg. F. in superheat was obtained, the flue-gas temperature was reduced 70 deg. and the draft was reduced 38 per cent.

Changes of the extension grates did not have the desired effect, although it is believed that further study will develop better arrangements of air openings and possibly reduce ash-pit losses. Air leakage from the chamber below the stokers was found to be as much as 25 per cent. at high ratings. As much as 2.6 per cent. increase in efficiency was obtained with the best coal tested, but clinker trouble was experienced, so that one of the grades giving only 0.6 per cent. increase in efficiency was preferable. Energy for boiler auxiliaries averaged between 0.7 and 1.6 per cent. for light load and 170 to 200 per cent. rating. Considering all economic factors, twelve and a half hours was determined as the most desirable interval between blowing of flues. The coal required for banking in excess of four hours was found to be 8,600+105× hours for floating bank and 8,00+280 ×hours for dead bank. A study of heat absorbed indicated that five rows of tubes between the upper center drum and each mud drum and ten rows of tubes in the outer banks are more desirable than are the present arrangements.

In the discussion of this paper great commendation was expressed concerning the accuracy and value of the investigation. The expense of such tests, while great, is well justified by the higher efficiency and superheat obtained, declared Dr. Jacobus.

Determination of Pipe Bends

As a result of mathematical study and tests, Sabin Crocker and Sterling S. Sanford presented charts which can be used in selecting the proper size and shape of bends to care for a given expansion and in determining the force exerted by a bend in state of deflection. In general the authors recommend bends of larger dimensions than ordinarily used. Their figures are said to be on the side of safety. In some cases the bends tested showed greater flexibility than was anticipated.

While the contribution of Crocker and Sanford was commended, attention was directed by at least two speakers to apparent oversights that make the calculated results differ from test results. The advisability of considering expansion loops made of straight pipes was suggested by a few speakers. Some questions were raised regarding the effect of pressure and temperature on the flexibility and stress in pipe bends.

W. B. Campbell contended that even some of the conclusions from actual tests are not accurate because they are based on ideal conditions.

This contention was carried still farther by Robert Crane, who said that the assumption that the neutral fibre runs through the center of the pipe bend does not result in accurate conclusions. Furthermore, he contended that the fact that some of the calculated results were greatly different from test results should be sufficient reason for thoroughly investigating the cause.

More attention must be given to flexibility of and stress in pipe bends, asserted F. Hodgkinson. Flexibility can often be obtained with loops composed of straight pipes instead of fancy bends. To permit alignment of pipes more consideration must be given to torsional flexibility and means for allowing it.

J. V. Brady related some trouble with bends which had not been properly annealed. They tended to straighten after being placed in service. He also advocated more consideration of straight-pipe loops, saying that no excessive pressure drops had been experienced with an extensive installation of such expansion loops at Hell Gate.

Mr. Whitney called attention to some U bends which did not allow the deflection calculated, whereas double-U bends allowed more than twice the deflection. He contended that designers need not fear ripples or buckling on the inside of pipe bends since they reduce stress in outside fibres and increased flexibility. Seamless tubing was urged for bends requiring large-diameter pipe, because with its use there is not the danger of rupturing the outside of the bends.

John Stevens referred to installations in which flanges had failed without the bends showing signs of weakness. In Europe, he pointed out, reservoirs are being extensively installed between the steam mains and the turbines. Duplication of such practice was recommended in this country.

George Orrok raised a question regarding the effect of operating steam pressures and temperatures on the fibre stress and deformation in pipe bends.

Feed Heating for High Thermal Efficiency

The problem of determining the correct feed-water temperature for high thermal efficiency was presented by Linn Helander. He considered a 25,000-kw. station, investigating the conditions when using single-stage and multiple-stage condensate heaters, both with and without economizers and treating the subject from the viewpoint of thermal efficiency only. For power plants using single and multiple stage heaters of the condenser type, the temperature of the boiler-feed water as it leaves the heater should not be less than 150 deg. F. when using economizers and not more than 260 deg. F. when not using economizers. Heat balances showed that when using single-stage heating and no economizers better results were obtained from heating the feed water by combining steam from the house turbine and that bled from the main unit than when using the steam from a house turbine alone. Double-stage heating with no economizers also showed better thermal efficiencies when using a larger amount of steam from the main unit than from the house turbine.

The increasing tendency to bleed the main units for heating the feed water with the consequent decrease in use of house turbines was the keynote of the discussion. W. M. Keenan said that in the new Brooklyn Edison plant the heaters will be supplied with steam by bleeding the main turbines. He pointed out that for a single stage the best bleeding point is between 20 lb. and 30 lb. absolute pressures. For two stages the best points are 12 lb. and 100 lb. absolute pressures, respectively.

Commenting on modern practices as to the use of house turbines, Prof. A. G. Christie said that in the future large stations will use one or possibly two of these turbines, the main supply of steam for heaters being taken from the main turbines. O. F. Junggren and F. Hodgkinson both expressed the same opinion basing their remarks on the fact that much better over-all efficiency can be obtained by bleeding the main units. Ideal operating conditions, according to Mr. Junggren, depend on producing the maximum power in the turbine and heating the feed water to the limit by bleeding. Mr. Hodgkinson pointed out that turbines of modern design are now provided with four bleeding points, namely, 140 deg. F., 200 deg. F., 50 lb. and 120 lb. absolute pressure.

Higher Pressures and Temperatures

Higher steam pressures and temperatures were the subject of considerable discussion. Two papers on the subject were presented—one by George A. Orrak and W. S. Morrison, the other by B. N. Broido. In the latter paper were given results of tests to determine the heat-transmission coefficients of bare and covered pipes at different steam velocities, superheats and pressures. Suggestions were made regarding velocities to select for best economy of transmission.

The discussion from the floor went into practically every phase of this subject—early attempts at high pressure operation, the question of whether higher pressures and temperatures are the way to greater economy, need of balancing fixed charges against fuel cost, possible effect on continuity of operation, effect of prolonged high temperature on metals, value of alloys for fittings, serious problems with pipe flanges, experiences with high pressures and temperatures in the oil distillery field, need of standardizing pipe fittings, economy of regenerative cycles or superheating between stages, higher pressures versus refinement in operation and the use of factor turbines. Every one agreed that reliability and continuity of operation are paramount and that efficiency, flexibility of operation and simplicity rank about on a par in consideration of any new design.

O. F. Junggren contended that past experience has not indicated so far that we have reached the economic limit of pressure, and that engineering ingenuity can be expected to solve all problems.

H. D. Hibbard emphasized the necessity of investigating the effect of continued high temperatures on the elastic limit and tensile strength of metals.

Gun steel, he declared, reaches its maximum tensile strength at 950 deg.—about 300 deg. above steel used in power plants.

Dr. D. S. Jacobus pointed out that the problem in using higher pressures and temperatures is more with pipe fittings and flanges than anything else, owing to the falling off in elastic limit. Flanges must not spring or distort and hence they cannot have an extreme overhang.

Referring to experience in the oil-distillery field with high pressures and temperatures, Mr. Millikan declared that valves have been in successful operation at pressures and temperatures up to 1,200 lb. and 1,000 deg. superheat respectively. The chief requirement in such valves is that they shall be made of acid open-hearth steel, be symmetrical and have no flat surfaces and be carefully annealed.

W. J. Wohlenberg contended that there is no need of economizers if the regenerative cycle is used. Mr. Orrok maintained that the more times steam is taken from an expansion stage and returned to the input side the higher the economy will be.

Several speakers, notably I. E. Moultrop, contended that before going to higher pressures and temperatures more attention should be given to refinements in operation. John Stevens presented curves which indicated the effect of coal cost and load factor on efficiency and first cost, while Peter Junkersfeld called attention to the use factor of a number of turbine installations running from twenty to thirty hours per year up to six thousand to seven thousand hours per year. He pointed out that whereas the use factor of one-year-old turbines may be only 44 to 58 per cent., it drops off rapidly as the turbines get older, owing to the economy of using a more modern turbine.

On Wednesday night the American Society of Mechanical Engineers held a joint meeting with the American Economic Association. E. M. Herr, president Westinghouse Electric & Manufacturing Company, and Prof. W. C. Mitchell of Columbia University were the principal speakers. — Electrical World.

John Irving, general sales manager of Nova Scotia Steel and Coal Co., is dead. Mr. Irving was president of the Hattie Gold, and while visiting the property he contracted a severe cold which resulted in his death. He was at one time a resident of Toronto and was a member of Toronto Lacrosse Club.

Port Arthur, Ont.—With twenty-three vessels in port one day recently the Port Arthur-Fort William harbor presented a scene of great activity. Fifteen of the largest vessels on the lakes were loading grain; twelve vessels were expecting to clear during the day, taking out 3,225,000 bushels. This is the largest single day's shipment by water so far this year.

Slag Encrusted Boiler Tubes

An elaborate report on a class of boiler trouble, which fortunately does not often worry English engineers, but is more or less prevalent in America, has been made by Mr. Harry H. Bates, one of the stoker engineers of the Westinghouse Electric and Manufacturing Company, Philadelphia. The report deals with the formation of slag on the tubes of water-tubes and the possibilities of its prevention.

At the commencement it is pointed out that "it is a daily occurrence to hear of boiler stations operating at 300 per cent. of rating or more, and it is by no means unusual that 400 per cent. of the rated capacity and more are reached." When boilers are forced to such an extent it is only natural that difficulties should be experienced which would not develop in more normal circumstances, and the choking of the passages between the tubes is among them. The extent of the trouble may be gauged from the photographs we produce, which show the accumulation of slag during less than a week's working, at the end of which, it is said, the boiler ceased to operate.

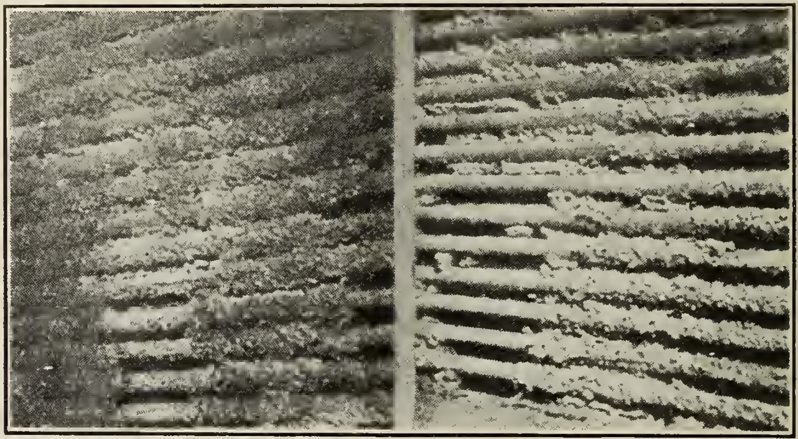

Fig. 1.

The author of the report gives particulars of the principal constituents of coal ash, from which it is assumed the slag must come, and shows that none of them is fusible individually at ordinary furnace temperatures. When, however, they are intimately mixed with basic oxides the melting point is so much reduced that the mixture will flow in the boiler furnace. Such oxides are provided by the pyrites commonly found in coal. The fact that this impurity may be the cause of the trouble is borne out by the fact that some American coals, such as Pocahontas and Elkhorn, which contain very little pyrites, give a minimum of clinker trouble. It is the ferrous oxide produced by the pyrites which reduces the fusing temperature of the slag, while ferric oxide results in a comparatively infusible material.

Mr. Bates suggests that minute particles of slag are carried up from the fire even when the gases are rising at a comparatively low velocity. When these little particles come in contact with the free oxygen in the furnace gas for a sufficient time completely to oxidise them they become solid. If they solidify before touching the tubes or walls they are carried through the boiler as solid ash. On the other hand, in the event of no free oxygen being obtained through the fuel bed, the particles remain in a molten condition, on account of their low fusing temperature in their -ous state, and are deposited on the tubes and walls, where they may either be completely oxidised and solidified or be covered by successive coatings or layers of the same plastic material. That the latter is true to a large extent is shown by layers of a very dark vitreous material covered by a reddish brown layer or protective coating. This reddish coating is largely ferric material, and it prevents further oxidation of the dark ferrous material within by excluding the oxygen from it. A considerable portion of the material on the outer surface, especially on the tubes, is of a friable and non-fusible character, and it is of a completely oxidised nature.

Analyses of the slag taken of various parts of the boiler, where it was more or less liable to oxidation, confirmed the theory that it was necessary to oxidise the ferrous into ferric iron and several means were tried for introducing the necessary oxygen. One of the most promising experiments consisted in raising the boiler so that the height from the fire to the tubes was increased from 13ft. up to 19ft. with the idea of lengthening time during which the globules of slag were exposed to oxidation from 0.72 second to 1.05 second. The change did not, however, prove very effective, and had the disadvantage of exposing more brickwork to high temperatures.

Mr. Bates goes on to argue that furnace construction undoubtedly has much to do with the external encrustation of the tubes with slag. The ratio of the exposed tube surface to the grate area in the case under review was 1 to 1,

Assembling Parts By Pressure At The Bench

When the Hammer May be Used to Advantage—Steady Pressure Best for Accuracy—Special Fixtures for Locating to Exact Position—Means of Supporting the Work

By FRED HORNER

THE hammer as an instrument for putting together or dismantling tight-fitting parts now holds a secondary place alongside the alternative of forcing by screw or lever pressure. This is particularly so in cases where injury or distortion of the piece must be avoided. In mere breaking-up processes the thing is to do the job in the shortest time, and blows or pressure are used indifferently, according to which gives the quicker results. Frequently a few smart blows will start a hard fit or rusted joint immediately, and here discretion must be exercised, if hammering can be safely done. In considering the small class of forcing that is practicable on the bench, we are faced with the choice of three methods—the vise, the arbor press, and screws or bolts. Each has a sphere of its own. The vise is very powerful, but slow, and owing to the vertical attitude of the jaws, some articles (with their packings which may be necessary,) are awkward to keep in position. The arbor press offers the advantage of a horizontal surface, and is much quicker in operation. It also provides a greater amount of "daylight" than the vise, and freedom below for the projection of shafts. The bolt method generally comes in for situations where neither of the other appliances are available, owing to the conformation of the work, or because it is partly assembled. And, of course, away from the shop, bolts may play a much more important part, as there might not be any convenient alternative.

Use of the Vise

In the vise, the usual objects dealt with are rods, plates, wheels, gears, etc. that require to have pins or bushings forced into or out of them. The chief aim lies in taking the pressure against the piece in such a manner that distortion, or risk of fracture are not likely. Pressure must be preferably localised around the area of the hole where the pin or bush fits, and not allowed to reach to a rim or other distant part. Risks of the sort just mentioned are thus eliminated, and the pressing becomes more effective. Danger of marking finished surfaces exists, from the serrations on the jaws, and so the packing at the back serves a double purpose. Fig. 1 shows the ordinary disposition of the parts, including packings, for pressing in a bush, and Fig. 2 a plan of the opposite condition, that of extraction. Rear packings (or a tube) with clearance are likewise necessary if a pin or bush requires to be pushed into a rod so as to hang out, instead of lying flush. The assembling of parts such as strips or discs with two or more pins concerned sometimes involves the preparation of a special pad or die to effect an even pressure all over the surface, and at the same time clearing the pins.

Special Pad or Die

Fig. 3 gives such a rig-up where three or four pins have first to be pressed into the bottom plate (A) and then plate B pushed down to a certain distance. The pressing plate, C, enables this to be done accurately, the distance between the plates being ascertained by a gauge or other means. Tube packings of small diameter are useful for taking the pressure at the back of an awkwardly-formed article, liable to tilt more or less out of truth when merely resting against the jaw. The tube just surrounds the hole where the pin is forced in, or rests on an equivalent area, so that the resistance comes in exact line with the direction of forcing. An encircling tube offers advantages for some sorts of pressing, in which close contact without risk of slip precludes the use of separate strip packings. This is evident from Fig. 4, illustrating the pushing off of a ferrule from a bush. A similar arrangement suits for forcing on, with the difference that a reduced support such as drawn at the end would not be necessary. If pressing on to an exact distance, not evidenced by the presence of a shoulder as a guide, is wanted, such distance from the end of the work can be controlled by making the forcing ring of suitable length, so that when the ferrule has been thrust far enough, the vise jaw will come into contact with the end of the work.

Accurate Locating

Besides the limitations imposed on length between the vise jaws, there is also the disadvantage that wheels and other specimens extending out some way from a shaft cannot be got into the vise for forcing, hence the arbor press is preferable in regard to these two points. Methods of ensuring a definite degree of projection depend upon the number of articles to be done. For one, or a small number, the mode of actual measurement of work is sufficient. For batches of pieces, the ram may be fitted with a strongly-clamped ring encircling it above the bearing, and adjusted after the first sample has been

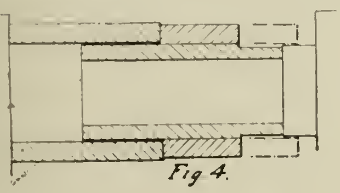

Fig 4.

pressed. The possible uncertainty, due to the chance of slip of this collar, may be abolished by applying a ring around the pin, after the style drawn in Fig. 5. Shouldered pins, judged by sight as to the flush state of the shoulders, may be pushed a little too far, and then have to be retracted; to avoid this waste of time a close-fitting washer (see Fig. 6) underneath the job will be useful, arresting the shoulder positively. The use of a plate slightly larger than the bush, Fig. 7, is also recommended for flush pressing, in circumstances where the underside of the bush cannot be met and checked by the table or plate.

Bolts and plates chiefly come in when large wheels, frames, and so forth cannot be put in the vise or the press. Methods of application are generally simple, comprising a stout bolt and two plates or hair-pin clamps, one spread over the hole at the rear and the other comes against the bush, the nut being tightened until the latter is home. Solid holes in the wheel or arm spaces or apertures in a framing are essential to permit a set-up resembling that illustrated by Fig. 8 to be employed. A like affair can be utilized to force bushes out, interposing a piece of shaft between the top clamp and the face of the bush, the shaft being just small enough to pass into the wheel hole.

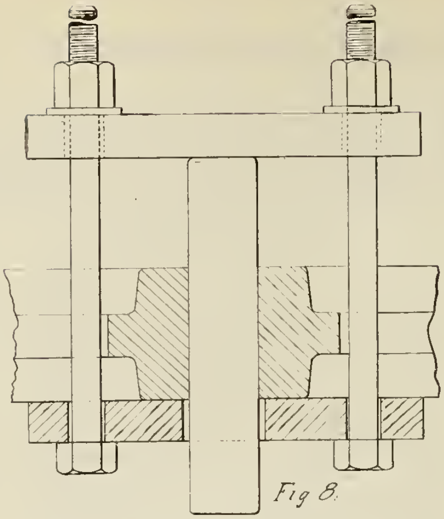

Fig. 8—Rig-up for forcing pin in wheel.

TESTING THE EFFICIENCY OF LEATHER BELTING

Tests made of leather belting by the Leather Belting Exchange, Philadelphia, show that, with a reasonable shop tension, a transmission belt with its flesh side in contact with the pulleys will average only about 50 to 60 per cent. as much power as when the grain side is in touch with them. On the other hand, at higher tension, the flesh side will do much better averaging from 50 to 100 per cent. more power than the grain side, the results depending, of course, on the belt and the conditions of service. For the experiments five 4-inch 30-foot, single belts of different make, weighing from sixteen to eighteen ounces, were used. The conditions were standardized, and the belts were all thoroguhly "run in" before the tests were made.

The following test, conducted at the same time, strikingly illustrates the low efficiency of a new belt. When first put on the pulley, the belt transmitted 12 H.P. at a slip of 1.2 per cent. After turning for five hours it transmitted 19 H.P. with the same percentage of slip; after thirteen hours it transmitted 24 H. P.; while after twenty hours it transmitted 31 H.P. with a slip of 1.6 per cent. According to the horse-power tables its scheduled transmission should have been 26 H.P.

Worrying has the same effect upon your health and your mind that racing the engine while the automobile is standing still has upon a motor car. It uses up a lot of fuel and energy without getting you anywhere, and the more you do it the less fit you are to make any real progress.

MOUNT ROYAL HOTEL IN JAN. 20 POWER HOUSE

POWER PLANT equipment as installed in the new Mount Royal Hotel, Montreal, will be fully described and illustrated in the next issue of Power House, Jan. 20. While the grand opening of the hotel was celebrated Dec. 20, the actual finishing touches were not applied until the beginning of the new year.

The erection of this hotel has involved a heavy expenditure of money and the employment of a large force of laborers, mechanics and others who were kept busy for the past twelve months supplying and placing large amounts of material. The architects who designed the hotel were Ross & McDonald, Montreal, who are specialists in this class of work. They designed and erected the Chateau Laurier, Ottawa; the Fort Garry, Winnipeg, and the MacDonald, Edmonton. The designer was Water J. Armstrong, Montreal.

The new building has already been recognized by the architectural profession of Canadian and the United States as one of the most conspicuous buildings of its kind both from the viewpoint of architectural merit and building skill.

The general contractors, Thompson Starrett, Ltd., have had a very efficient staff of men on the job. The heavy stress and strain fell upon the shoulders of R. Miller, a comparatively young engineer, who acted as construction engineer for them.

From the viewpoint of the stationery engineer, the man whom the readers of Power House are probably most interested in is H. M. Bogart, the mechanical superintendent. He it was who had to see that everything mechanical is as it should be, and, as every construction engineer knows, his was the task of taking the "kinks" out of new installations.

The story of the power plant was written by the special representative of Power House, G. J. Soucy, an engineer of experience, who was right on the job, and has prepared a description that is at once interesting and reliable.

Combustion

WE CANNOT pick up a technical journal relative to engineering but what there is some bold reference if not a leading article upon the subject of combustion. This appears to be one of the most engrossing subjects we have before us at the present time and one of extreme interest both to the factory owner and the engineer. To the factory owner because it is likely to be the one place where he will be able to effectively cut down the cost of operation of his plant and this in no small measure; and to the engineer the place where, with a little careful investigation and research, he is likely to obtain some very encouraging results. It has taken the factory owner a considerable time to realize the saving that could be actually effected in burning coal in a furnace. Formerly it was just a case of burn it, and nothing further. Now after persistent effort on the part of the engineer, who in many cases has been actually instrumental in educating his employer to these views, he is beginning to realize that what can be done in large power stations can also be done in small plants. However, nothing can be effected without the co-operation of both owner and engineer.

During any period of trade depression, the factory owner who is sufficiently far-sighted will be going in for reconstruction or alteration where necessary and having his plant and system tuned up. This will prevent loss of time when the time arrives for the factory to be worked at full production. Now is the time then for investigation and research to be made and we certainly think that those engineers who peruse the contents of this issue will find much food for thought in the article by J. B. C. Kershaw, more especially where he alludes or makes reference to the use of pressure-gas-fired boilers with pre-heated air. The furnace designs are most ingenious and detailed particulars of the nozzles are given for the correct handling and regulation of the gas and air. The sketches embody new ideas which should prove to be very stimulating to those who are paying special attention to this subject. It may not be many years before our present-day apparatus will be a thing of the past, and more economical and effective apparatus will have taken its place. We are on the eve of some wonderful achievements in promoting better means of combustion. We are looking for results in the right spot, and it is the man who works diligently and applies himself to his task who will come out on top. Everybody is looking for more economical methods of burning fuel and there is not a plant in existence upon which some improvement could not be made. Every plant engineer should therefore be particularly receptive to new suggestions and ideas and after a little experimenting it may be possible that you tumble across the very thing the world needs. There may be a large number of engineers who may say the same as the little boy whose teacher told him that some day he might be president of the U.S.A., when he replied, "That he would not mind taking two bith for his chance." This may be how it strikes you at present, but in all sincerity there are very few inventors who did not accidentally tumble across their ideas, and in many cases they had been looking for something entirely different. However, keep your goal before you and with persistent effort progress is sure to be made. Try new ideas out where possible, but always keep an accurate tabulated result of your experiment. In a number of small plants it may be that the engineer has little or no equipment, but that should not deter his efforts. The instruments to be used need not necessarily be very complicated ones, and a man handy with his tools could make the majority of them himself. If you get stuck we would always be pleased to help you out no matter what your difficulty; and do not forget that whether you make a great achievement or not, you are working and heading in the right direction, and are always advancing.

Autogenous Welding

WHEN autogenous welding is concerned in respect to the repairs of a boiler, there has been nobody more liberal and willing than myself to recognize the advantages and economies of such a process, whether this be accompanied by the oxy-acetylene, hydrogen or other gas process, or by the electric arc, and to advocate its adoption wherever possible under existing regulations. The general rule to govern the acceptance of such welds for insurance purposes, is that prescribed by the Boiler Code of the American Society of Mechanical Engineers, par. 186.

There are then given ten illustrations where such work should be accepted or rejected.

From the foregoing it will be seen that the restrictions are manifold in respect to the requirements of such a weld and a man would need to know something about the design of a boiler, to be able to determine just where such a weld would be acceptable. We will presume, however, that repairs have been recommended and the next thing necessary is for the boiler owner to obtain a workman to put these into effect. In all probability he recalls having seen a signboard somewhere down the street that bears the inscription "Expert Welder" and the man is engaged to do the job. Perhaps we find out upon inquiry that he has only just recently started up in business, having taken a course of training, covering a few weeks, at one of the engineering colleges in one of the big cities. We do not protest against this man carrying on his business as a welder but he should be forbidden by law to touch a boiler with a view to repairing it. The Boiler Regulations in the various provinces are pretty rigid, wherein the Department clearly states the qualification required of the man who examines a boiler, but nothing whatever about the man who repairs it, which is a time when most special attention is required.

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

Question.—Gas engines appear to be regulated by two methods; the hit-and-miss type, which regulates the speed according to the number of explosions required and the throttle governor which regulates the speed by the control of the gas volume.

It is claimed by some, that the throttle governing system, uses considerably more gas than the hit-and-miss system, even when they are both tried out on the same engine. If this is the case with all engines, why use the throttle governor at all?

Brodie.

Answer.—The throttling governor is not the most economical method of running a gas engine, but it is the system that is most often used on account of it causing the least variation in speed in the engine. This is a most important factor when the engine is used for driving electrical machinery, or in the manufacture of various materials and fabrics in our factories.

At this point it would be just as well to explain that the function of a flywheel must not be confused with the duties of a governor. A flywheel is purely to absorb, or store up energy that is imparted to it during the impulse portion of the cycle. So that this energy can be again utilized during any portion of the cycle, until it receives another impulse.

A governor is designed to reduce variation in speed and maintain steadiness in running.

There are several methods of controlling and operating the speed of internal combustion engines:

1. By interrupting the sparking when electric ignition is used.
2. By cutting off the gas supply during any portion of the cycle.
3. By keeping the exhaust valve open or closed during one or two strokes.
4. By regulating or throttling the gas supply.

The first two methods are of the hit-and-miss type, and the second two can be classified as the throttle governor type. There is a third system which is a combination of these two methods, wherein the charge is throttled up to a certain limit and then cut off, but we understand this method is not very much in use.

If, therefore, the variation in speed in a gas engine is a negligible factor, the hit-and-miss control is the most economical means of operation, but where steadiness in running and uniform speed are required, a good type of throttle governor should be fitted.

ECCENTRIC PISTON RING

On the Question Box page of Nov. 20 Power House, there is an item re, "Size of piston rings" in which the questioner is advised to have the rings turned eccentric.

While it is true that rings of this form fit a cylinder bore more perfectly than when made parallel or concentric, I would not advise making them eccentric and for this reason.

The groove in piston must be deep enough to take thickest part of ring. In operation, a piece breaks off the thin end of ring, and works around until it jams under the thicker part. I have had that happen several times. In one case an 18 in. piston got caught, and as the piston rod was screwed into the cross-head it was some job backing it out.

Also for a 12 in. cylinder I would turn the rings 12⅛ in. dia. and ¼ in. to 5/16 in. thick. An 18 in. piston would have rings 18 3/16 in. dia. x ⅜ in. thick. Make groove in piston only deep enough to let rings in flush, so there will be no room for rings to vibrate.

W. C.

Question:—Where can one get an authoritative, up-to-the-minute book dealing with steam automobiles?

R. T. B., Forest.

Answer:—We are afraid there is no book published making a specialty of this type of car. It may be possible, however, that a number of articles have appeared from time to time in the various automobile journals and we think it would be a good plan for you to communicate with these papers when possibly you could procure some past editions which contain some information upon this subject.

We believe there is only one steam car in Canada and that is the Stanley Steamer, address 493 Yonge St., Toronto, who may be able to supply you with descriptive literature. The White Steam Car, we understand, has not been manufacturing since 1909, but it is possible they may very shortly go in for a heavy haulage car. The Detroit Steamer is a small car that will very soon be placed on the market in Canada, but up to the present there is no literature to be had on the subject.

STEAM FOR NOTHING

In many industries, notably paper making, dyeing, brewing and laundries a large amount of low pressure steam is required for heating purposes. The usual practice is to employ the exhaust steam from the engine which drives the factory; and the impression has long been common that the steam so obtained costs nothing. As a matter of fact, however, it costs a good deal, because an engine which does not condense is very uneconomical as a source of power, while it frequently happens that the heaviest demand for steam comes when the engine is running light. In order to solve this problem in a more efficient manner a leading British firm of engine builders have introduced a new type of engine from which the steam is obtained economically in a most ingenious manner. The engine is known as the "Candem compound"—there being two cylinders through which the steam passes in succession. The steam required for heating purposes is drawn from a point between the cylinders. When no heating steam is required the engine runs as an ordinary compound condensing engine while, when the demand for heating steam is great, practically all the work is done by the high-pressure cylinder. Taken all round, this arrangement provides the most economical way of meeting the two demands for power and for steam. Automatic gear is fitted to ensure that the heating steam is supplied at a steady pressure and that the engine runs at a constant speed in spite of change in the load or in the demand for heat. Tests show that the equipment results in a very large saving of fuel as against the use of separate boilers for the provision of power and the supply of heat.

St. John, N. B.—Dr. W. H. Collins, director of the Geological Survey, Department of Mines, on his return from a three weeks' visit to the various field parties who are at work surveying the mineral industry of Nova Scotia and New Brunswick, is most optimistic. He reports new coal beds the existence of which was unsuspected, and deposits of oil shale in both provinces, associated with coal measures. They are not yet being mined, but constitute the basis of an important future mining industry.

Operators' Point of View

BOILER COVERING

I expect a million words have been written in reference to the danger caused by allowing scale to collect inside a steam boiler, which may cause overheated plates and tubes and tend to hurry the act of crystallization or form other undesirable conditions.

There is, however, another dangerous condition often allowed in the boiler room, and a condition which may prove even more dangerous than scale. It is often overlooked because it is not so wasteful of the dollars as scale. The condition I refer to is moisture on the outside of a covered boiler. I saw one boiler top sand covered, with the top plates corroded inward nearly two thirds of their original thickness. This condition was caused by a drip from a leaking pipe which passed over the boiler. Another boiler had a leak at a pipe connection near the top of the boiler under the brickwork. The leak had been in existence probably for months before it was discovered, as the heat evaporated enough of the leaking water to prevent the remainder from dripping into the fire, but it kept the brickwork damp. A section of the plate containing several square feet was so badly corroded that a punch could be driven through it without difficulty with a one-pound hammer. Most engineers have noted how rapidly a hot pipe will corrode away if it is laid in damp ground. The same process operates upon the boiler shell if it is covered with a permanently damp coating whether of brick, sand, asbestos or other material.

James Noble.

Editor's Note:—Asbestos, sand or other forms of porous material are not usually objected to as a covering for a boiler, because any leakage that may occur in the steam is immediately made manifest on the outside in the form of a damp patch, and which gives the engineer in charge sufficient warning when caulking or repairs can be made. With brick covering, however, this dampness will never show on the outside and for this reason brick work is greatly objected to as a covering medium. Where it is used it should be completely removed from the boiler top at least once every three years, so that the plate and seams can be thoroughly inspected to insure that no concealed wasting is taking place.

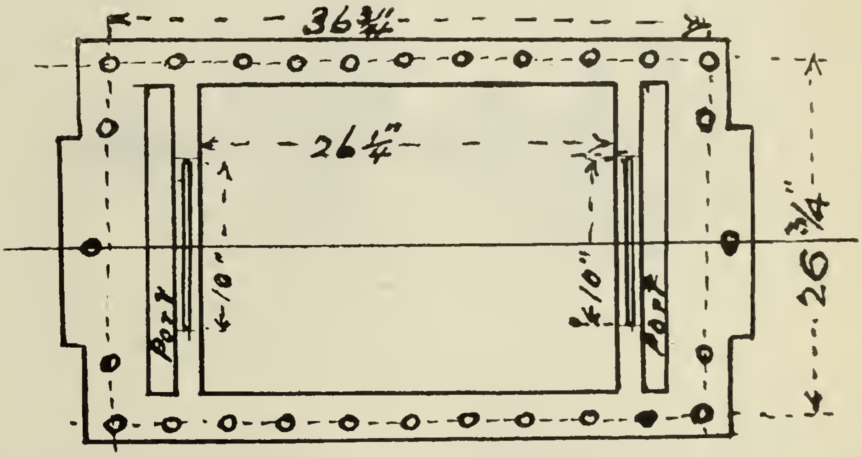
It is concealed dampness that is the danger in every case. If an engineer is aware that water is dripping from a steam pipe upon the boiler covering and percolating through to the plate of the boiler, it is up to him to stop the leakage immediately and not blame the insulating material for allowing it to soak through. Boiler insulating material should be porous and if the engineer watches out for the first indication of leakage in the form of a damp patch and immediately investigates the cause, there is little fear of concealed wasting occurring about the top part of his boiler at least.

PISTON VALVE CHAMBER

The piston valve chamber of a 24 in. x 36 in. horizontal engine was taken off to be rebored. It was noticed that the gasket was gone some 7 in. or 8 in. in the middle of the bars, allowing steam to escape to the wrong side of piston. Also by applying a straight edge to the faces they proved to be slightly hollow.

After reboring, some futile attempts were made at getting a joint to stay in but the job was satisfactorily accomplished by using two strips of copper ¼ in. x ½ in. x 10 in. long, let ¼ in. into the cylinder casting, and ¼ in. into the chamber casting.

The accompanying sketch shows the application of copper strips, the 1/16 in. gasket being cut away where the copper is let in.—Vancouver.



Gauge Glasses. Annealing important but certain conditions demand special treatment, such as where glass is subjected to great temperature and sudden changes of heavy shock and strain under these conditions of high temperature. This treatment requires careful study of strains and manner in which they are produced. Boiler gauge glass cut to length on wheel with wet abrasive and ground on wet stone stands up better than same piece of glass annealed. Need of healing by fusion of microscopic cracks caused by cutting with wire or wheel depending upon local frictional heat. Heat treatment consists in heating glass to 1,300 deg. F. (or other suitable temperature) and cooling very rapidly and evenly in the air and allowing it to become naturally strained. H. W. Hess, Glass Worker.

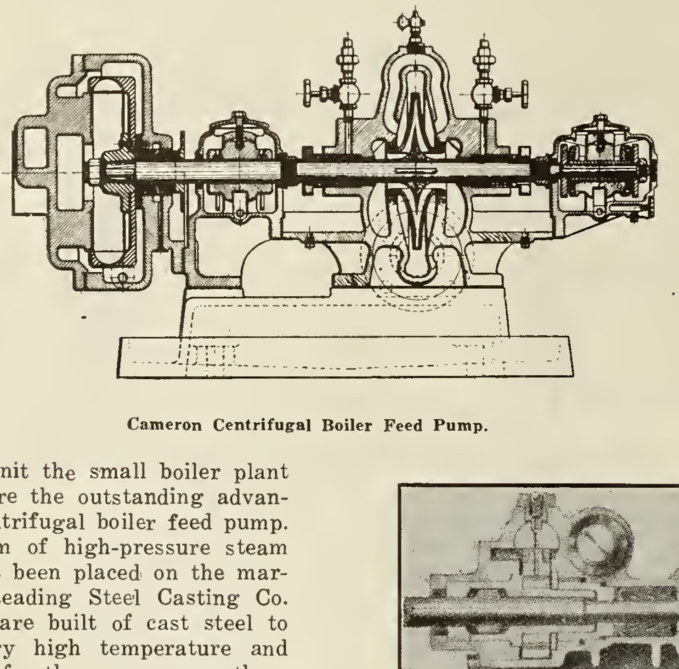
Hamilton Bridge and Iron Works have been awarded the steel contract for the erection of an addition to the factory of the Zimmerman-Reliance Co. of Hamilton. Steel sash work goes to the Trussed Concrete Steel Co., Toronto.

Corrosion. If oxygen of water can be removed and be prevented from re-entering, corrosion difficulties must ordinarily cease. Two ways of accomplishing this. One is to bring water into contact with large mass of replaceable iron or steel having large surface, so that oxygen can use itself up on low-priced metal. The corrosion method of removing oxygen from boiler feed water is exemplified in Europe by the Kestner process, in America by the Speller process. Description of Kestner "degasser," which is nothing more than tank full of steel turnings and provided with valves and piping of such nature that feed water may be passed through bed in either direction at will.—Industrial Digest.

Progress in New Equipment

The new Cameron single-stage, turbine-driven centrifugal boiler feed pump is designed for boiler plants having up to 2,000 boiler horsepower and using steam pressures of 150 pounds or less.

The outstanding feature of this pump is its simplicity. The single-stage impeller and turbine rotor are mounted on the same shaft. The absence of a coupling and the compact design results in a remarkably large capacity per unit of floor space required.



Cameron Centrifugal Boiler Feed Pump.

With this unit the small boiler plant can now secure the outstanding advantages of a centrifugal boiler feed pump.

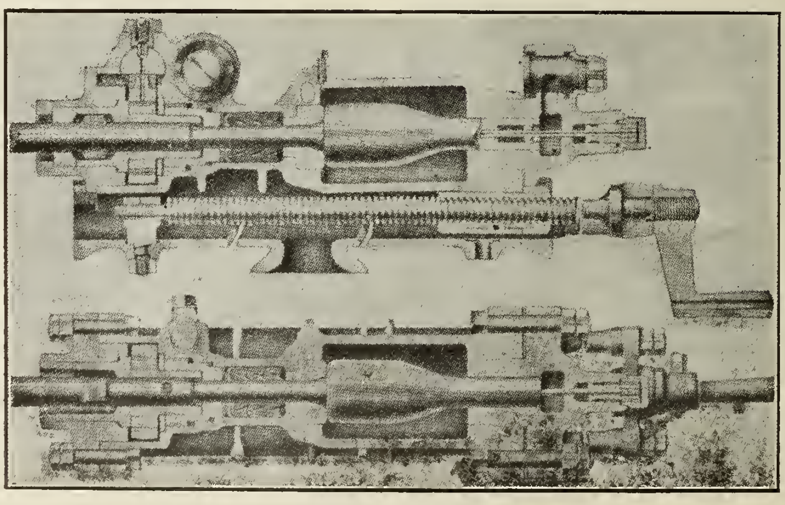
A new form of high-pressure steam valve has just been placed on the market by the Reading Steel Casting Co. These valves are built of cast steel to withstand very high temperature and pressures and for the same reason there are special features embodied in the design of the body and bonnet. The valve is equipped with a split wedge supporting two metal discs and mounted on an adjustable and universal stem-nut, giving the whole unit great flexibility and still remaining simple in structure and design.

Magnetic chucks are very efficient for holding small pieces for grinding, as the entire face of the chuck can be covered with such parts, thereby supporting each other firmly, so that a large number can be machined at one time, resulting in a much larger production than would be possible by handling the pieces separately.

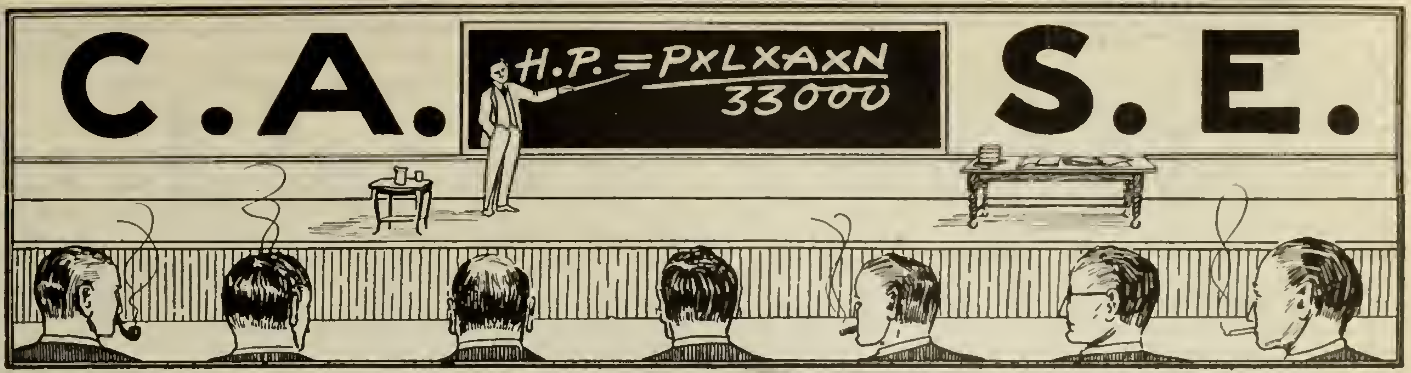
The Dustless Wave Rock Drill is operated by the pressure waves travelling periodically along the pipe, being fitted with a hammer element which is thrown forward by each wave of pressure. Surrounding the hammer is a space called a capacity, filled with water, and, due to the difference in diameter between the striking end and the piston end of the hammer, a displacement takes place on the forward stroke of the hammer which compresses the water in the capacity. As the pressure wave passes and the pressure in the line drops below the mean pressure, the force on the annulus being greater than the force on the piston end, returns the hammer back to the original position, ready to receive the next pressure wave. The apparatus used for this demonstration of this drill has been described as follows:

A steel vessel in the shape of a bottle, mounted like an ordinary gun, is filled with any liquid, and fitted to a rifled barrel. Between these two parts is a valve designed to act automatically at a pre-determined pressure. By means of an ordinary hand pump, connected by a copper tube to the bottom of the vessel, more fluid is pumped into it. The pressure of the fluid is thus increased to the pre-determined point at which the valve operates, and the energy which has thus been stored is released and acts on the base shell, which is projected through the rifled barrel in much the same manner as that when the customary propellor is used. The recoil is stated to be less than that experienced with the ordinary gun, and the barrel is not damaged by corrosion.

The Rock Drill has been designed to withstand the rough usage to which it is inevitably subjected under practical mining conditions. A distinct feature of this Rock Drill is the independent rotation of the drill steel; no splines whatsoever are required for this purpose. Any ordinary standard drill steels can be used and the cradle is made to suit standard rigs. Water—the medium for carrying the Wave Energy—is continuously passed under pressure through the drill point, which is easily controlled by the Operator. This water is used for washing out and turning into sludge the debris of pulverised rock as it is created by the Drilling.



New Wave Rock Drill.



A meeting of the Toronto No. 1 C. A. S. E. was held on Tuesday evening, Jan. 3rd, at Cumberland Hall. There was a very fair attendance of members considering notices had not been sent out, which was due to the sickness of the secretary, G. A. Browne. We feel sure that the friends of Mr. Browne will be pleased to hear that he has since recovered, also that his little son, who was knocked down by an automobile two weeks ago, is now fair on the way to recovery. Unfortunately his son had two ribs broken in this accident, when one of his lungs was punctured and he lay in a very critical condition for several days.

A paper was read on "Boiler Appliances and Accessories" by R. McLean, chief engineer of Massey Harris, which proved to be of a very interesting nature. Many questions were asked by the various members, and Mr. Bly, former president of the association, took an active part in the discussion and brought out some very interesting side lights. Particular attention was given during the lengthy controversy to the following subjects:

The action of springs in "pop" safety valves.

The action and ultimate effect of vacuum and pressure upon the hollow elliptical tube of the mechanism of a pressure gauge.

Some troubles that have developed in different plants with water-columns and the water pipe connections.

The cause of fusible plug failures.

A discussion on the different types of blow-down valves, dealing with the comparative merits of each, and giving the objections to various kinds of gate valves.

It is possible that a number of these questions will be revived at some future meeting.

SOME CURRENCY

We are informed that rye is to be the medium of exchange in Oldenburg, Germany. Rye notes are to be issued based upon the value of rye and will be worth a certain quantity of rye. After four years, the holder of the notes is to receive the gold value then prevalent for the amount of rye indicated on the certificates.

What would some of the old timers have thought about a "Rye" currency in Canada, at least for a week or two over the Hogmanay.

ANNUAL BANQUET

On the evening of Dec. 20 the Atlas Engineering and Machine Co. and the Grant E. Cole Co., of Toronto, held the first of what the management hope will be their annual banquet at the Walker House, Toronto. A splendid program was carried out, made the more spicy by song and music from Messrs. W. Dawson and Fielding. Splendid addresses accompanied the toast. Mr. A. C. McNaughton proposed a toast to "Our Organization," responded to by L. S. Elsie. Mr. McNaughton briefly outlined the story of the birth of both companies and their association with each other. Mr. Elsie's reply was apt and manifested the spirit of aggressiveness on the part of the company. A toast to "Our Products" was moved by Mr. W. Williams and responded to by Geo. E. Cole.

Canadian industry was toasted by H. D. Tresidder, responded to by Major Anthes. The theme of both these gentlemen's remarks dealt with the wonderful development Canada had made industrially, and the particular relation thereto of the products of the companies under whose auspices they were meeting that night. They urged loyalty on the part of every employee from message boy to president, loyalty to the product, to the company, and to the field they were serving. These features, they said, formed an important place in a healthy development of Canadian industry. Mr. Attwood, the inventor of the Attwood pump, was enthusiastically received and told the story of his life's association with this industry. The following members of the staff and friends were present:

G. Smart, H. Attwood, A. Northern, Z. Turner, S. Glasier, H. Moore, N. W. Kingsland, H. D. Tresidder. Major Anthes, Capt. Watherspoon, T. M. Jones, C. Cox. F. Dawson, A. K. Fielding. L. S. Elsie, G. E. Cole, H. Augur, W. Jamieson, S. Roberts, A. C. McNaughton. W. W. Attwood, H. Angus, W. Williams. E. Jones. H. Fletcher, A. Howarth. F. Haskell, J. Seed.

It seemed rather strange that such an early opportunity should have been given to Mr. Attwood, who, after having spoken at some length about the development of his pump, was almost interrupted in his remarks by the announcement from the check room man that the coat of Mr. Auger was leaking. At first it was thought a pumping demonstration was to be given, but it was found afterwards that this unfortunate occurrence had nothing whatever to do with Mr. Attwood's remarks and that the report was nothing but moonshine.

NEW BOOKS

Steam Vessels by the National Boiler and General Insurance Co. Ltd., of Monchester, England, 8½ x 5½ inches, 40 pages, price 2/-.

This book treats in a very liberal way with the design, construction and working of vessels subjected to steam pressure, and contains 35 illustrations. It deals primarily with kiers, digestors, concentrators, stills, drying cylinders, etc., with line drawing describing the apparatus, also defects and wasting that are liable to occur and how to obviate this by inspection. It should prove to be particularly useful to the manufacturers and users of such apparatus who wish to promote greater safety in the use of such appliances.

NEW PUBLICATION

The power equipment of the plant of the Marquette Cement & Manufacturing Company, Lasalle, Ill., is described in a leaflet published by the De Laval Steam Turbine Company, of Trenton, N. J. In this plant direct current is used for the operation of cranes, hoists, crushers and other machinery, and is found of particular advantage where variable speeds are required. The current is supplied by a direct current generator of 3,750 kw. capacity, driven by a De Laval compound geared turbine. The latter has two shafts, the pinions of which drive the gear coupled to the generator shaft. This arrangement makes it possible to combine a large number of turbine stages, as required for high efficiency, with the advantages of short, rigid shafts. Cement dust and other impurities, such as water, sludge, and lint are removed from the lubrication system by a centrifugal purifier made by the same company.

Port Arthur, Ont.

Plans are being prepared for terminal elevator to cost $900,000 for N. Bawlf Grain Co. Ltd., 571 Grain Exchange, Winnipeg. Work will be done under supervision of the Engineers, C. D. Howe & Co., Whalen Bldg., Port Arthur.

SLAG ENCRUSTED

(Continued from page 34)

which, he says, is very low, and the lower the ratio, under set conditions of fuel and fuel bed, the higher will be the furnace temperature. It is apparent that the higher the furnace temperature the greater will be the tendency for the ash to fuse and stick. It has become common practice now to have the ratio of exposed surface to grate surface as high as 1.87 to 1, and is seldom less than 1.2 to 1. By increasing this ratio the amount of heat radiated up and absorbed is very materially increased, with a consequent reduction in furnace temperature. Unfortunately, the construction of the investigated installation did not permit changing the ratio, and, for comparative purposes, it was necessary to refer to a neighboring station with a similar type of stoker and boiler, and using a similar coal. This second plant has had practically no trouble with slag on tubes, and uses only the soot blowers while the boilers are in operation.

An interesting difference in the two stations was the first two rows of tubes in the former were staggered, and slag impinged on and stuck to both rows. The second row caused more trouble than the first row, as the slag took the form of icicles or stalactites, and when they became long enough and the velocity of the gas became high enough, the "icicles" bent sideways until they touched the lower tubes. This effectively sealed the gas passage of that part of the boiler. The second installation had the first two rows set one above the other. The material which struck the bottom row of tubes adhered, but the rapidity of the formation was far less. On account of this arrangement, the gases were sufficiently cooled by passing between these tubes to prevent the slag from sticking to the higher tubes, and there was no further tendency for this slag to adhere to the boiler surfaces.

When it is considered that the ash is very finely divided in the coal, and that some of it is certain to be carried up with the gas, it appears that the most fruitful field for development of means for slag prevention is in furnace and boiler design. This belief has already been justified. At the same time there is still need for further development of apparatus for mechanically removing soot and slag from boiler tubes.—The Engineer.

St. John's, Nfld.—According to report, the British Treasury has signed a guarantee for $10,000,000 recommendation of the Trades Facilities Commission for the establishment of pulp and paper mills at Humber, Newfoundland. The Newfoundland Government has guaranteed the contractors, Armstrong Whitworth Company, a similar amount. The initial work has already begun.

WORKING INSIDE OF BOILERS

Some time ago, two boiler makers were badly scalded while working inside of the mud drum of a water-tube boiler. A new mud drum had been connected to the boiler, and when it was tested leaks were found, and it was necessary to do some calking and riveting in order to make the job tight. The boiler was set in battery with a number of others which were under steam, and all the boilers were connected to a common main blowoff pipe. The stop valve in the blowoff pipe leading to the new mud drum had been closed, but for some unknown reason it was afterward opened and left open. This latter fact was not known to the man in charge of the boiler plant, however, and he, assuming that the stop-valve was still closed, proceeded to blow down one of the other boilers. Some of the escaping steam entered the new mud drum through the open blowoff valve and caused the accident of which we are speaking. The cries of the scalded men were unheard, but one of the victims succeeded in crawling out of the drum, and he then closed the valve and so made it possible for his companion to get out.

Unfortunately, accidents of this general nature occur every little while. They are wholly unnecessary, because they can be prevented by merely closing, and keeping closed, all valves which may admit steam or water to a boiler in which men are inspecting, cleaning, making repairs, or doing other work. The mere closing of the valves is not enough. That is quite evident, without any argument; and if it were not, the example we have given above, would prove it. The valves must be kept closed. In practice, too many men have access to them. If only one man were allowed to operate them, and he were known to be thoroughly competent and responsible, the possibility of accidents would be greatly reduced; but the moment we depart from this principle, and let two or more men tinker with the valves at will, the hazard becomes very real and serious, because each man is altogether too likely to assume that somebody else has taken the necessary precautions.

There ought to be a cast-iron rule in every plant, requiring men who are about to enter a boiler to give notice of their intention, first of all, to the chief engineer, or the person in charge of the boiler-room. The man in authority should then close the valves himself, or name some one particular individual and instruct him to do so; and the man in charge should also take effective measures to prevent anybody else from touching the valves again, until he gives further orders. After the valves have been closed they should be locked, or protected by placing locked shields or covers around the valve wheels or handles. When the work inside the boiler has been completed, and all the tools and materials have been removed, and the men have come out for the last time, they should report to the man in charge of the valves. Then, and only then, the valves may be opened without danger of scalding somebody.

Montreal.—An extension to the departmental store of the Henry Morgan Co. will shortly be proceeded with by the Morgan Realities Co. The main frontage of the new building will be on Union Ave., and will run northward from the present store on St. Catherine St. In addition there will be built a new central steam heating plant at the corner of Aylmer and Mayor St. The heating plant will contain four 200 h.p. water tube boilers by Goldie & McCulloch Co., Galt. The boilers, 160 lbs. pressure, will be equipped with improved side dump stokers by the Underfeed Stoker Co. of Canada, also Diamond valve-in-head type of soot blowers. The stokers will be designed to operate at 200 per cent. of rating. Provision will be made in designing the boilers so that superheaters may be added later if desirable. The vacuum system of heating will be used and the heating load is estimated to be about 800 horsepower. The plant will be so designed that the coal will be dumped or unloaded from trucks direct into large coal hoppers in front of the boilers. The coal, as required will be discharged first into a combined lorry and thence directly into the stoker hoppers.

Of the steam jet type, a modern ash conveyor will be installed to remove the ashes from the basement and discharged then into a large elevated storage bin outside the building. Trucks will load direct from the storage bin hopper and transferred thence to a convenient ash dump.

Alex. Wilson, Montreal, is the designer of the new building and heating plant.

STAINLESS SURFACE TO STEEL

The discovery of a process for the electrodeposition of chromium on any metal article is reported from Sheffield, England. It hinges in part on the discovery of stainless steel, but unlike previous discoveries along that line, it deals with a surface treatment of the article only. It not only makes the surface stainless and permits a high polish to be put on it, but it is said to be cheaper than ordinary stainless steel in the production of large articles. The surface of the treated article is very hard, and the deposit is not likely to wear off. One of the difficulties, however, is to prevent stripping or peeling, which is often seen in silver-plated articles.

What is believed to be the thickest seam of black coal discovered in the world is being exploited in Queensland, Australia. The seam is entirely free from clay bands and is 93 feet thick in places. The mine is 280 miles from the nearest seaport.—Dearborn Independent.

Electric Cranes

We manufacture high class Electric Cranes of every type and for every purpose.

Overhead Travelling Cranes for the most onerous work of lifting a complete locomotive or for the exact work of handling moulds and molten metal and for ordinary requirements where lightness and speed count most.

Giant, Goliath, Gantry and Transporter Cranes for shipyards, railway yards, and general manufacturing purposes.

ELECTRIC CAPSTANS

Travelling and Stationary Jib Cranes with fixed radius jibs or fitted with Patent Balanced Lever-Luffing Jibs for use on docks, in shipbuilding yards and other places where the load must be handled at speed between obstructions that necessitate the radius to be altered frequently and as a part of the "cycle of operations."

SHEER LEGS to which Luffing-Jib may be applied.

CHARGING MACHINES for Open Hearth and Re-heating Furnaces.

WINCHES AND HOISTS

Electric Portal Jib Cranes fitted with Patent Balanced Lever-Luffing Jibs

Conveyors

for handling raw materials such as coal, coke, ashes, clinker, ore, stone, lime, etc., automatically and with a minimum of labour.

The B. & W. line of Mechanical Handling Machinery includes Bucket and Tray Conveyors, Suction Ash Conveyors, Automatic Railways, and all the details thereof including coal and coke breakers, loaders, dumpers, weighing machines, etc.

We shall much appreciate an opportunity of going fully into details of any of our manufactures with intending purchasers.

What is PLIBRICO? JOINTLESS FURNACE LINING

PLIBRICO is a plastic furnace lining in unbaked form that meets all furnace requirements and that can be installed by anyone who can use a mallet and trowel. When baked, it forms a one-piece, jointless furnace lining that is resistant to temperature to 3,100 degrees F.

PLIBRICO outlasts ordinary fire brick two to four times. It eliminates the joints—the root of all furnace trouble—and so gives a lining which will not crack, fall off or bag.

Write for new fifty page booklet

It is delivered only in steel containers of distinctive appearance as shown below.

Emergencies Prove Its Superiority

It may not be often that the oil film fails in any of your bearings, but the possibility is always present. It is emergencies such as this that test the value of your bearing metals. Magnolia Anti-Friction Metal protects your shafts and bearings from damage in such temporary contingencies. With the lowest frictional coefficient of any known bearing metal—proven by U.S. and foreign government tests—it runs cool with less lubricant and is a safeguard against hot boxes and melting out where lubrication is neglected or may fail for any reason.

Try out a sample Magnolia-lined bearing and test its many advantages for yourself.

TRADE MARK

The C. P. R. are contemplating the erection of a new hotel in the Laurentide mountains.

Canada Sugar Co., Montmorency street, are about to remodel their power plant. Chas. E. Burows will be in charge of alterations.

Announcement is made that the General Engineering Co. will succeed the firm of Gelinas & Pennock, Montreal. The new firm, in addition to the lines formerly handled, will add the following: London Steam Turbines, Troy, N. Y., and Flexatilac Gasket Co., Camden, N. J. They expect to open a branch office in Toronto to handle their Ontario trade.

Chas. A. Sargent western manager for Darling Bros. Ltd., engineers, formerly of Montreal, died at Chicago last month after a short illness whilst on a business trip.

Mr. Sargent, who lived in Winnipeg, was prominently identified in sporting circles and was also a member of the Kiwanis Club in that city. He was born in Montreal 44 years ago. At 14 years of age he entered the business of Messrs. Darling Bros. Ltd. as an apprentice and remained with them until the time of his death, having worked his way up until he became western manager, he being the firm's oldest employee.

NEW BOOK

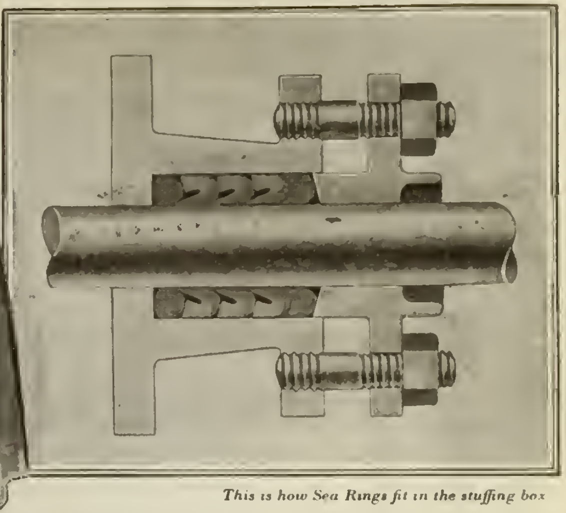
We have received from the branch office of the Ingersoll-Rand Co., 260 St. James St., Montreal, a book illustrating many of the products of the company, amongst which are sections given to ammonia compressors, oil engines, air compressors, electric hoists and marine oil engines. This book deals with the design and efficiency of various machines and is beautifully illustrated.

Lubricating Oils. Lubricating distillates require further refining. Chemical treatment consists in thoroughly mixing distillate with sulfuric acid and allowing sludge to settle. Oil then transferred to second agitator where it is neutralized with caustic soda or other alkali. It is then washed with water to remove the excess of alkali and the alkaline reaction products. Disagreeable odor of lubricating distillates due to sulfur and nitrogen bodies. Sulfuric acid treatment removes unsaturated hydrocarbons, sulfur and nitrogen compounds and asphaltic and bituminous substances. Details of process given.—Petroleum Age.

High-Pressure Steam Heat. The use of reducing valve in a steam-heating line does not, in itself, have any effect on the economy of the heating. If a steam motor is substituted for the reducing valve, the heating value of its exhaust is decreased by the amount of heat turned into work by the motor. Line drop is merely distributed throttling and has no direct effect on the final heating value of the steam. By generating at high pressure and transmitting through a small line, with large line drop, the heat loss from the line may be made much smaller than when the pressure is low throughout the system. E. Buckingham. Mechan. Eng.

Passenger steamers in the Canadian service head the list among the large steamships built during the year, according to Lloyds Register of Shipping report, just issued. Thirty-two ships exceeding 10,000 tons are listed. Of these the Canadian Pacific "Empress of Canada," 21,517 tons, in service between Vancouver and the Orient, was the largest Canadian steamship.

Plant for the reduction of bituminous coal into coke at Sydney, N. S., is being considered by the Government as a safeguard against recurrent coal strikes in the United States. The supply from the proposed Sydney station would be designed especially for central Canada. A similar station may be established in the west if necessary, but it is calculated that British Columbia or Alberta coal either in its natural form or as briquettes, will not come east of Winnipeg.



This is how Sea Rings fit in the stuffing box

An *Idea*—

not a tradition— made this packing

Nothing in the engineer's list of materials has seen so little change in fundamental design as ordinary rod and plunger packing. The Johns-Manville Sea Ring represents the first radically successful improvement since the first stuffing-box was invented.

Sea Rings pack by "self-expansion"—not by gland pressure. The cylinder pressure they pack against is trapped in the U-shaped section causing the lip of the ring to automatically press against the rod to prevent leakage. The force of the lip pressure varies with the cylinder pressure so that packing friction on the rod is reduced to the minimum never more than necessary.

Minimum friction means minimum packing wear—Sea Rings last years where ordinary packings last months.

It also means power saved—One test on a triplex pump showed a saving in electric driving power of $55.91 a year per stuffing box.

Sea Rings are far more economical than ordinary packings.

DO YOU Manufacture Industrial Equipment?

Are you a manufacturer of twist drills, hack saws, mechanics' tools, wire guards, bolts, rivets, paints—do you manufacture lines of any description that can be used in machine shops, metal-working plants, power plants or foundries? If you do the publications you see illustrated here (Canadian Machinery, Canadian Foundryman, and Power House) can build a bigger demand for your products.

This group of technical newspapers is read by the men who are prospective buyers of your lines. You can bring to the attention of these men the reason why they should demand your goods when purchasing from their dealers. You can effectively do this by placing a message in the paper which serves the field in which your products are sold.

CANADIAN MACHINERY AND MANUFACTURING NEWS is published weekly and covers the machinery, iron and steel and general metal-working industries of Canada.

POWER HOUSE is published twice a month; it serves steam, electrical, water and gas power plants, and the power houses of all general manufacturing plants.

CANADIAN FOUNDRYMAN AND METAL INDUSTRY NEWS is published monthly; it serves the grey iron, steel and non-ferrous foundries.

These publications reach proprietors, managers, purchasing agents, foremen—the men who direct the purchasing of goods. A message to these men in any of the MacLean Technical Newspapers is certain to have a strong influence.

Write for complete Data.

If The Pressure Becomes Excessive

Untold damage may result if fixtures are not protected. Preventive insurance by the use of a Mueller Relief Valve can be had at slight cost. Built to give service and satisfaction, each valve adapted for its particular installation it will fulfill the requirements in every instance.

It is dependable under all circumstances, does not stick even after long periods of inactivity and responds instantly when service is demanded.

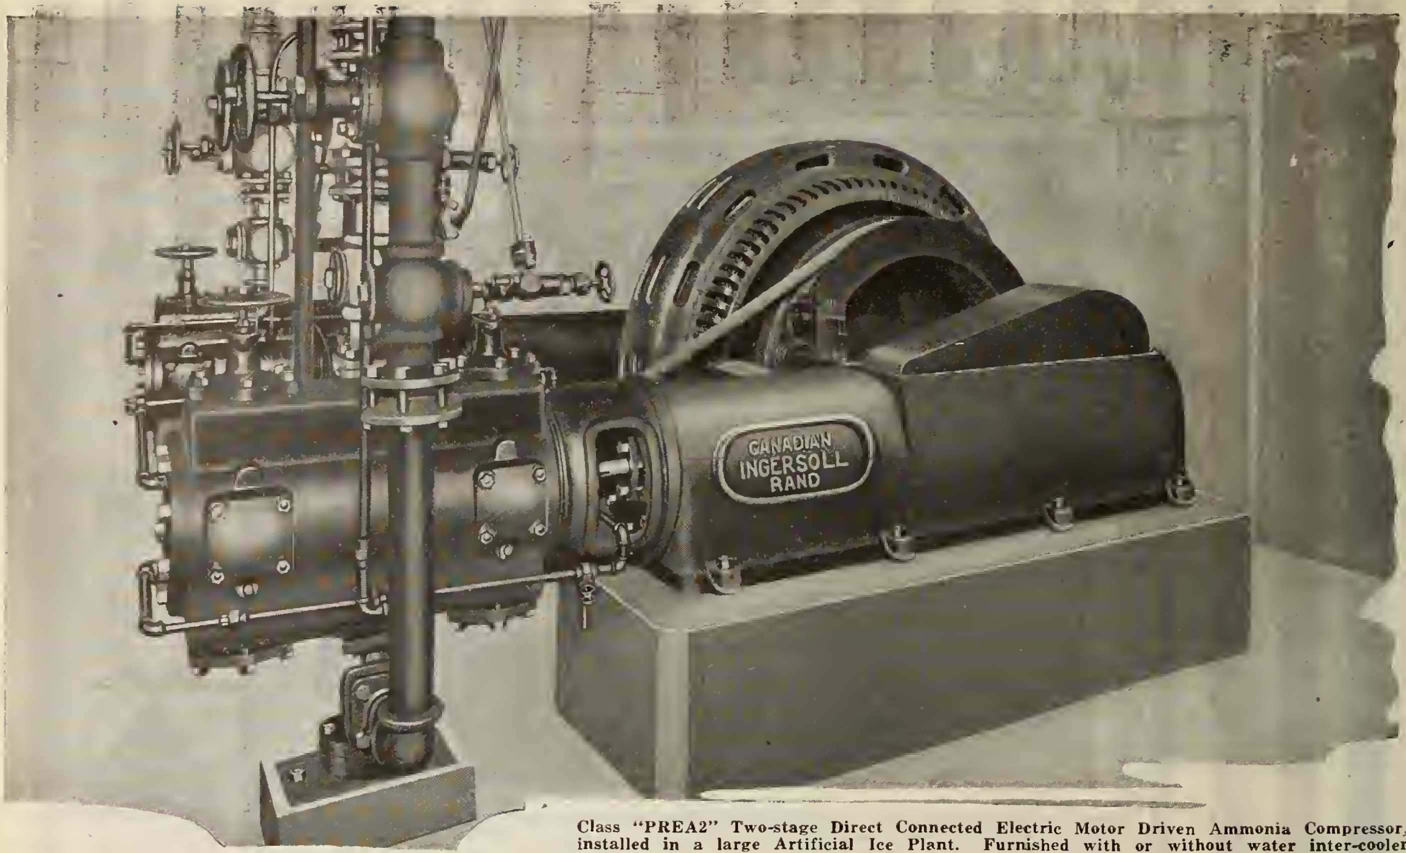
Highly sensitive, positive in action, easily adjusted—it provides the Factor of Safety for all steam, air, oil or water lines.

H. MUELLER MFG. CO., LIMITED, SARNIA, ONT.

Water, Plumbing and Gas Brass Goods and Tools.

American Factory at Decatur, Illinois, U. S. A. **Branches, New York and San Francisco**

Mueller Metals Co., Port Huron, Mich., Makers of "Red Tip" Brass Rod; Brass and Copper Tubing: Forgings and Castings in Brass, Bronze and Aluminum; also Screw Machined Products.



Class "PREA2" Two-stage Direct Connected Electric Motor Driven Ammonia Compressor, installed in a large Artificial Ice Plant. Furnished with or without water inter-cooler between stages.

Ingersoll-Rand

Ice and Refrigeration Plant Equipment

Ammonia Compressors
Built for either single or two stage operation, and for belt, steam, oil engine or direct connected electrical motor drive.

Air Compressors
Can be furnished in all sizes and for any commercial discharge pressure. These units are particularly suitable for supplying air for agitation, Air Lift Pumping or for general power purposes. Any type of drive.

Air Hoists
Built in five sizes for from 1,000 to 10,000 pounds capacity. These hoists are extensively used for lifting ice cans and for general hoisting work. They are easy to move about the plant, and simple to operate.

Pneumatic Tools
A complete line of riveters, drills, grinders, etc., for erection, assembly and repair work.

Cameron Pumps
For pumping brine, water and other liquids. These can be furnished in direct-acting type for steam or compressed air drive, or in centrifugal type for belt, motor, steam, oil or gas engine drive.

Price Oil Engines
Of the direct-injection, four-cycle type. Horizontal, single cylinder types of 50 and 100 H.P., and vertical, multi-cylinder types from 105 to 1,000 H.P.

A.C.-1.

Announcing
INGERSOLL-RAND AMMONIA COMPRESSORS

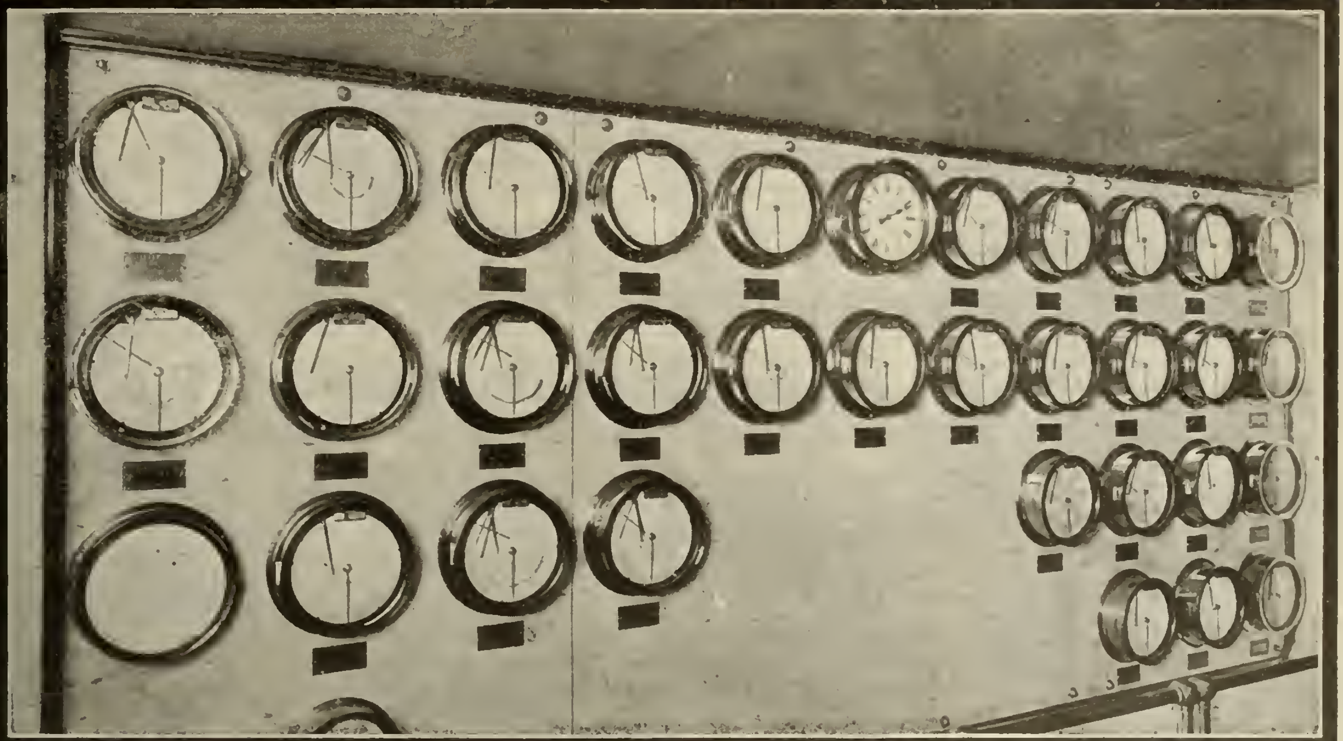
The Canadian Ingersoll-Rand Company take pleasure in announcing that they are now offering a complete line of Ammonia Compressors, designed especially to meet the requirements of modern raw water ice manufacturers, ice cream factories and cold storage plants in general.

These Compressors are available in straight line and duplex types and for belt, steam, oil engine or electric motor drive. They are built in sizes suitable for small, medium or large plants and embody every feature that tends to provide for high economy in operation.

Descriptive literature and complete information regarding any or all types will be promptly furnished on request.

Ingersoll-Rand

Drills Condensers Vacuum Pumps Gas Compressors



A SHINING EXAMPLE

OF THE POSSIBILITIES IN INSTRUMENT CONTROL

We make Indicating and Recording Liquid Level Gauges, Thermometers, Pressure Gauges, CO2 Recorders, etc., for use on:

- *Boilers*
- *Feed Water Heaters*
- *Economizer Inlets and Outlets*
- *Steam Lines*
- *Flue Gases*
- *Condenser Discharges*
- *Hot Wells*
- *Turbine Exhausts*
- *Turbine Bearings*
- *Turbine Oil Pumps*
- *Generator Fields*
- *Fuel Oil Pumps*
- *Fuel Oil Storage*
- *Transformers, etc.*

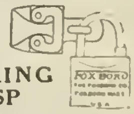
Constant and intelligent use of the instruments illustrated above enables one of New York's largest hotels to insure the comfort of its guests twenty-four hours a day, 365 days a year. At the same time, the close control which these instruments make possible has brought about very important savings in coal.

The thirty-two Foxboro Instruments record temperature of hot water for laundry, kitchen and house, temperature of drinking water, boiler feed water, city water, ground floor ventilation air, outside air temperature, low pressure return and outgoing brine temperatures on ice machines.

The pressure gauges record pressure of city water, high pressure air system, house hot water, hydraulic elevator, boiler "blow down," high and low pressure steam returns, annex steam heating system, boiler steam pressures, house heating system and ammonia pressure on ice machines. A Foxboro Liquid Level Gauge records depth of water in tanks on the roof.

The Foxboro round case and inverted pen arm account for the neatness and compactness of the board and the clean records produced. Time has demonstrated the wisdom of choosing Foxboro Instruments which combine permanent accuracy with long life. Their superior construction and quality of workmanship is the real reason why engineers everywhere place their confidence in Foxboro as "The Compass of Industry."

Write to Dept. C.F. for information on the application of Foxboro Instruments to your problems.



SPRING HASP

This is the latest of the many exclusive Foxboro features which take Foxboro out of the class of ordinary instruments. A push of the hand—the Spring Hasp closes the case dust-tight automatically, thus assuring a clean record and protecting the mechanism at all times.

Representing the Leading Manufacturers

In addition to manufacturing and distributing Fairbanks-Morse products, The Canadian Fairbanks-Morse Co., Limited, represents the leading manufacturers of mechanical goods.

When ordering from our nearest branch, you are ordering from the manufacturer whose product has proved itself the acknowledged leader in its particular field. Here are some of the well known lines we handle:—

- **Fairbanks Scales**
- **Pratt & Cady Valves**
- **Palmetto Packing**
- **Strong Steam Traps**
- **Allen Engines**
- **Landis Threaders**
- **Graton & Knight Leather Belting**
- **Yale Chain Hoists**
- **Gould's Pumps**
- **Fairbanks Valves**
- **Durabla Packing**
- **Foster Regulators**
- **Fairbanks-Morse Gas and Oil Engines**
- **South Bend Lathes**
- **Dick's Balata Belting**
- **Norton Grinding Wheels**
- **Fairbanks-Morse Generators**
- **Fairbanks-Morse Pumps**

Each department is in charge of men who can give you valuable help in the solution of your problems.

36-48 Youville Square
Montreal, Que.

If your Supply House cannot supply you with Smooth-On —write us direct.

Feed Your Engine Dry Steam

When supplied with dry, hot steam, it's natural that your engine should show greater efficiency than when supplied with steam saturated with moisture. The installation of the

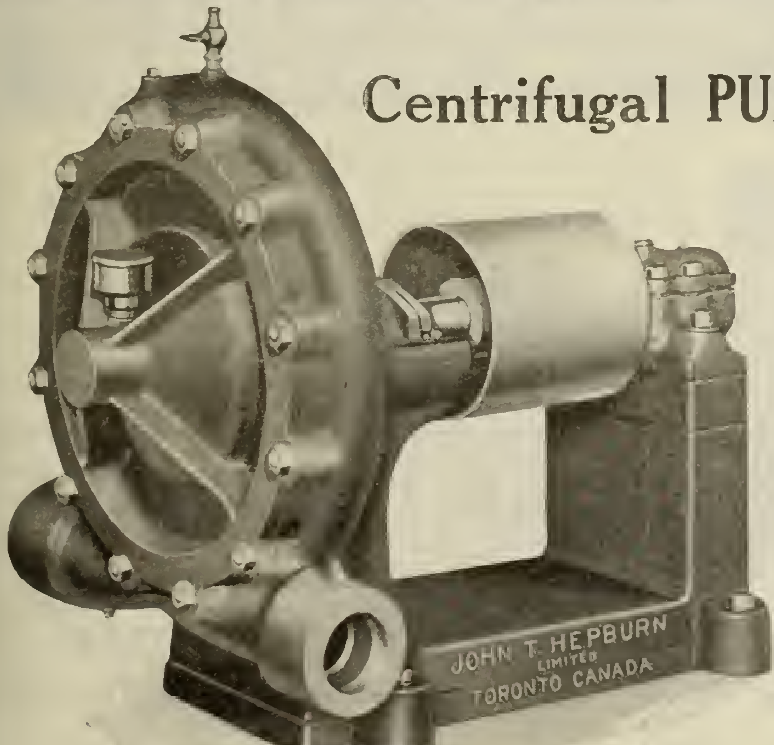
ANDERSON STEAM SEPARATOR

ensures a supply of dry, hot steam under all conditions and is a safeguard against the possibility of breakdown. Its action is positive and the moisture, once separated, cannot be picked up again.

You really need the Anderson—let us tell you more about it.

THE V. D. ANDERSON CO.
West 96th St. Cleveland, Ohio

Centrifugal PUMPS Reciprocating



The selection of a pump, be it large or small, certainly involves an important responsibility, for few buyers can afford the expense and trouble which usually follows the installation of unsuitable or low grade equipment.

All we ask is that your judgment be based solely on our pump and your acceptance given only after its pumping capabilities have been proven conclusively.

We can also quote attractive prices on cranes, derricks, hydrants and all kinds of special machinery.

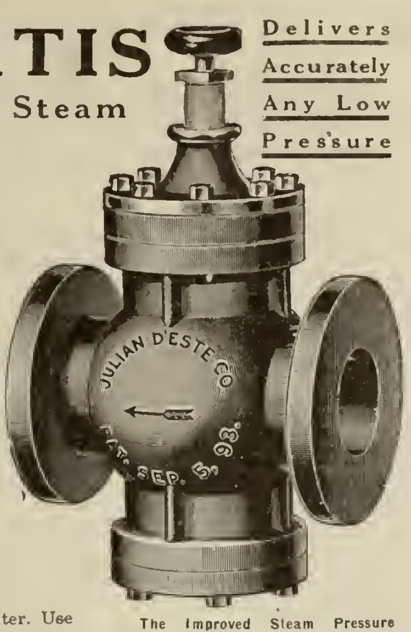
CURTIS

Improved Steam Pressure Regulator

Delivers Accurately Any Low Pressure

A compact, self-contained Regulator suitable for any boiler pressure. It delivers accurately and uniformly any lower pressure from one to within a few pounds of the initial pressure.

It has no levers, weights or projections; no glands or packing; no drip or leak of steam or water. Use it for efficient service on steam-heating apparatus, slashers, jacket kettles, air or water pumps, pulp mills, etc.



JULIAN D'ESTE CO.
PAT. SEP. 5, 93.

The Improved Steam Pressure Regulator is a lock valve, very simple and sensitive. Send for descriptive pamphlet.

JULIAN D'ESTE COMPANY

Main Office: 26 Canal St., Boston, 14, Mass.

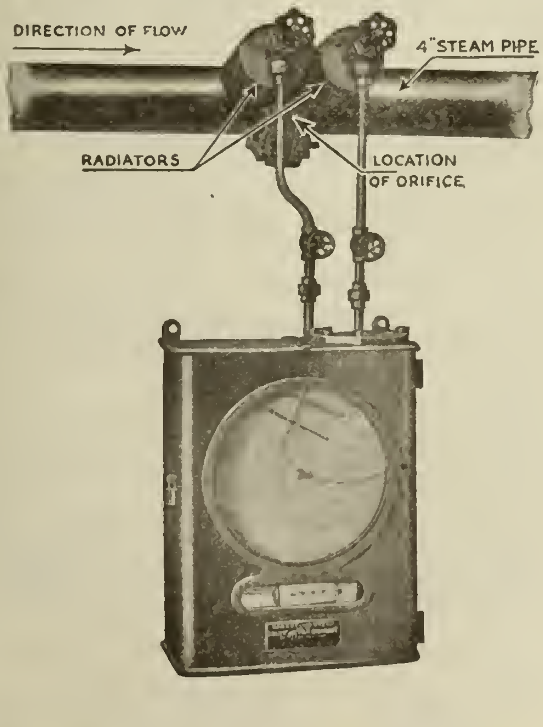
DE LAVAL Oil Purifiers are keeping clean the lubricating oil used in America's largest power plants. In smaller plants, such as the one pictured here, they are just as economical and efficient.

There is a De Laval Purifier to fit **your plant.** Bulletin 105 will tell you all about it.

The De Laval Company, Ltd.

Montreal Winnipeg Peterborough Ont. Edmonton Vancouver

It Will Pay You to Meter Your Steam



BAILEY FLUID METERS

Usually the purpose of a fluid meter is to measure the total flow, but it is equally important that the rate of flow be recorded continuously to show the variation in certain operating conditions or demand, or else to indicate whether or not certain conditions have been maintained as desired.

Even though an operator uses a flow meter only for the purpose of regulating a process, it is important that the meter draw a continuous record so as to show at all times how closely these results are being accomplished.

The accuracy of Bailey Fluid Meters for this service is unquestioned. Bulletin No. 31 describes them fully. Shall we send you one?

Every Engineer, Mechanic and Electrical Worker will welcome this new master set. It will answer your problems.

It will help you with your daily work.—A sure source of advancement and higher pay. Complete up-to-date information that is thoroughly and easily explained on every branch of modern engineering and electrical practice.

AUDEL'S ENGINEERS & MECHANICS GUIDES
4750 PAGES $1 A MONTH
8754 ILLUSTRATIONS $12 COMPLETE

These Guides tell you all about—

Theory, Practice and Operation of ALL Steam Engines; UNIFLOW and POPPET VALVE ENGINES, and LOCOMOBILES. Locomotive-Marine Engines; Turbines; Rotary Engines--the Indicator--Lubrication--PRACTICAL MANAGEMENT. GAS, GAS ENGINES--*Aeroplanes* and *Aviation*--HOW TO SELECT AN ENGINE. STEAM ENGINE rules and formulae. Steam Boilers; Heat-Combustion; Fuel and Flue Gas Analysis-C02 Recorders-Construction of all types of Boilers,--Mechanica Stockers--Oil Burners--Setting--Chimneys--Mechanical Draught--HOW TO SELECT A BOILER--BOILER DESIGN based on A.S.M.E. BOILER CODE--OPERATION FIRING. Pipes, Fittings--Heating and Ventilation--Refrigeration- Cooling Towers--Condensers--Distilling Apparatus--Elevators--Cranes--Ropes and Cables--Splicing--*Practical Electrical Engineering* as an aid for engineers and electricians in obtaining a license--ready reference index, covering entire field of Modern Electricity.

SHIPPED TO YOU FREE

Not a cent to pay until you see the books. No obligation to pay unless you are satisfied. Send coupon now--today and get this new master set for engineers. Pay only $1 a month.

Tycos and Steam Pressure

Where accurate measures of steam pressure and temperature are essential there is a *Tycos* recording pressure gauge or a *Tycos* recording thermometer to do the work thoroughly. These are especially efficient on long steam pipe lines where pressure measurements are required at both ends.

Request our catalog for power plants.

Columbia
Recording Thermometers

This advertisement is one of a series, each one of which covers one of the many "Columbia" exclusive features. In this way we believe we can best meet the inquiries we are constantly receiving for definite information.

THE ACTUATING MEDIUM

The actuating medium of the "Columbia" Recording Thermometer is Mercury, the standard basis of temperature measurement. Its superiority as the actuating medium of the industrial thermometer is attested by the fact that it is employed in all thermometers of the glass tube type where accuracy is essential. The most sensitive test thermometers and delicate clinical thermometers are mercury actuated. That is why mercury is employed in the "Columbia" because it is the only substance having all the fundamental requisites necessary to measure temperature with absolute accuracy, being extremely sensitive and responding instantaneously to the slightest temperature changes. And the action of mercury is uniform. The record given by the "Columbia" can, therefore, be relied upon as being absolutely accurate and true.

"SAFETY"
Plastic
Metallic
Packing

For steam, water, air, gas, etc., is practically indestructible and may be used over and over again. It is

Packing in Cotton Tubes

GUARANTEED
TO LAST THREE YEARS
WITHOUT RENEWAL

It is made of an alloy of the finest anti-friction metals, just hard enough for long service but not hard enough to damage any rod. The metal is combined with the best lubricating material, making it practically SELF-LUBRICATING AND FRICTIONLESS.

Send for full particulars also about our "Safety" Superheat Sheet Packing.

Packing in Bulk.

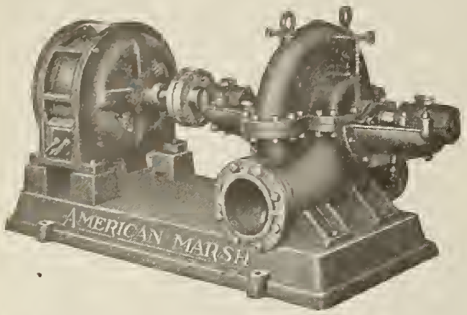
AMERICAN-MARSH PUMPS

Centrifugal and Direct Acting



Designed for use in power plants where absolute reliability and high efficiency are essential. For over thirty-five years American-Marsh Pumps have been recognized as standard throughout the Dominion. There are over 160,000 in successful operation.

The sturdy rugged construction and heavy cast bronze fittings insure long life and a minimum repair expense.

American-Marsh Centrifugal Pumps are built with the same painstaking care that characterizes the construction of the direct acting line.

The Line includes:

Boiler Feed Pumps
Air Compressors
Deep Well Engines
Centrifugal Pumps
Jet Condensers
Vacuum Pumps
Condensation Pumps
Sump Pumps

Dependable Everywhere

Yearly lack of up-keep cost is the only true measure of a valve installation.

Genuine Jenkins Valves

have a fifty-eight years' record of economical and trouble-free service in factories and buildings everywhere.

Because genuine Jenkins Valves are **made** to serve and **tested** for service before they leave the factory.

So that the Jenkins name, within a Diamond mark—the stamp of the genuine Jenkins—is to-day rightly regarded as the guarantee of valve dependability.

Descriptive literature telling about Jenkins Valves in detail will be mailed you on request.

A Time and Labor Saver

JENKINS

RAPID ACTION VALVE

Wherever an easily operated quick opening valve is desired there's a need for a Jenkins Rapid Action Valve like that shown here.

This Jenkins model opens with a slight pull of lever, stays open automatically, and closes with slight pull of lever.

An ideal valve for Laundries, Creameries, Shower Baths, etc.

Valves are made of bronze and are fitted with Jenkins Renewable Composition Disc, suitable for service required.

Write for full details of this time and labor saver.

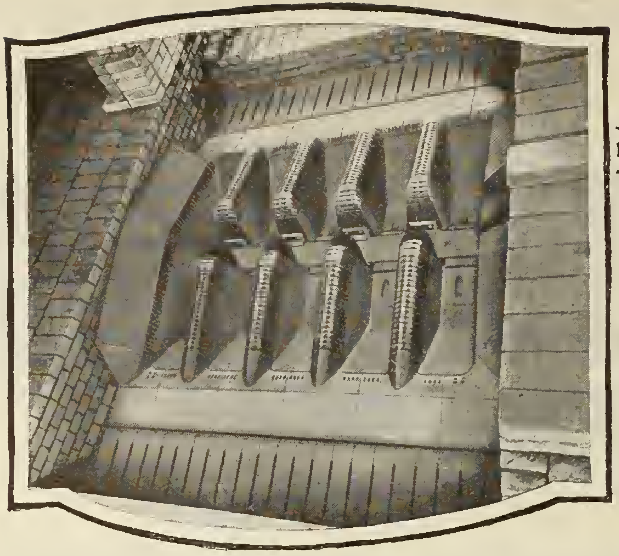
BRANTFORD, ONTARIO, CANADA



Trade-mark

"Lateral Retort" is a trademark. It is known by this sign: the arrows show the path of fuel travel.

Sectional view

It fulfills conditions met by no other stoker!

THE *"Lateral Retort"* Stoker should not be considered either as a substitute for, or an improvement on, the multiple retort type of stoker. It is rather a new type of multiple retort stoker—a type that makes multiple retort stoking possible in many plants that otherwise would be compelled to install an inferior type of stoker.

By embodying a multiple retort arrangement in a single stoker that follows the general design of simple side-cleaning stokers, a number of problems are solved in a remarkably simple way.

For instance, the necessity for basement ash pits is eliminated, since an excavation of 6 to 18 inches provides sufficient space for the two pits into which the ashes are discharged by the simple, side-dump plates. This greatly reduces installation cost and makes the "Lateral Retort" Stoker highly adaptable to old boilers in existing plants. Moreover, since the stoker is set very low, ample combustion space is insured when it is placed under low set boilers. Thus in many ways the "Lateral Retort" Stoker stands alone. It is the only side-cleaning stoker in which the coal is underfed throughout, giving the greater fuel economy and overload capacity of multiple retort stoking; and therefore it is the one moderate priced, economically installed stoker that in any way rivals the multiple retort type.

Conditions met by no other stoker. Are they your conditions?

The catalog will help you decide.

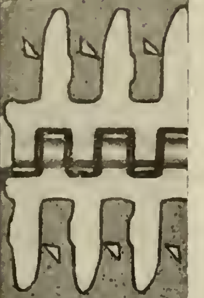
ALLIGATOR

TRADE MARK REG. U.S. PAT. OFFICE

STEEL BELT LACING



Why Men Change to ALLIGATOR

Strength comes first in belt lacing. Then follow: durability, ease and speed of application, efficiency in service, range and cost.

Alligator is the Strongest Belt Lacing on Earth—and the most permanent. It is applied with a hammer in an average time of only three minutes.

Mechanically perfect because it binds the long burden bearing belt fibres in equal service. "Every Tooth A Vise." Rocker steel hinge pin endures in any service where the belt will run. The finished joint is flexible, separable and smooth on both sides.

There is a size for every thickness of belting and the price is so reasonable that **its use immediately becomes an economy.**

If you are not using Alligator now, write us for sample and our interesting book "Short Cuts to Power Transmission." A trial of Alligator will be no less convincing than an analysis of its points.

Sold through "Jobber-Dealer" trade channels the world over.

"JUST A HAMMER TO APPLY IT"

"Never Lets Go"

The Safe and Certain Boiler Cleanser

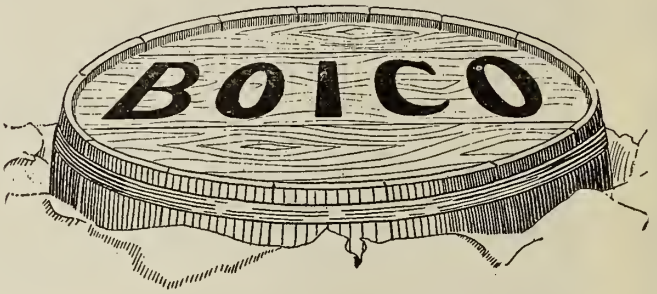
PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.**

BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.



Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

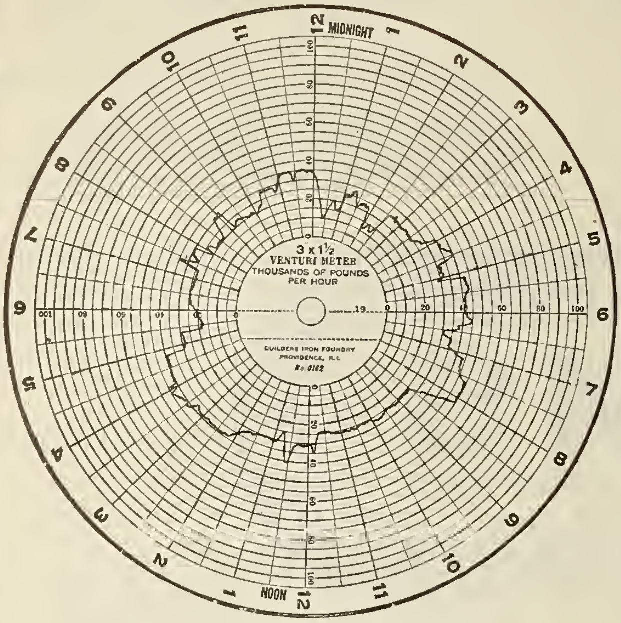
BUILDERS VENTURI IRON FOUNDRY



A Venturi Meter Chart
Showing Economical Boiler Feeding

Squeeze the B.T.U.s From Your Fuel

With the mounting cost of fuel, the problem of economy in the boiler plant becomes still more important. A strict and careful watch must be kept of this end of an industrial establishment if the cost of the finished products is to be kept down. Many thousands of power plants have installed one or more

VENTURI

"VENTURI"—Registered.
Boiler Feed Meters.

to give accurate daily records of how steam-making units are being operated. The Venturi is durable and needs little attention. It indicates the momentary rate of flow, registers the total flow and makes a record of the flow on a 12-inch chart. It is the standard meter for boiler feed measurement.

SPIRAL EXPANSION

Gives Longer Life

Instead of an annularly corrugated expansion element, the Radiator Trap Sarco contains a spirally corrugated tube. With this design the movement at any turn of the tube is so slight as to be hardly detectable. The movement is distributed over the whole area instead of being confined to a few points, and this lengthens the life of the tube and the efficiency of the trap.

Wear on the valve is minimized, too. The bronze metal cone, which fits snugly into the socket seat, works freely in all directions, distributing wear evenly and insuring perfect contact at all times in the

RADIATOR TRAP

SARCO

Another feature of the Sarco that adds to its long life is the construction which prevents scale and dirt collecting in the valve. Line contact only is had between the cone and seat of the valve and this makes it practically impossible for scale to collect. The Radiator Trap Sarco is of unusually heavy construction and it is factory adjusted.

Other important advantages are explained in our Booklet J-107. Send for it.

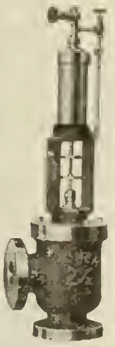
FISHER

TRADE MARK
REGISTERED



20 Years— Still in Service

W. B. Brady, Superintendent of a nationally known organization, says:

"The Fisher Governor which we installed in 1903 on our hydraulic pumps is still in service. Considering the length of time this governor has been in service, it is hardly necessary for us to give our opinion of its worth."

Fisher Pump Governor

(Type 1)

is our regular piston type governor which is so widely used and recommended for the automatic control of pumps. It is used on steam turbines, underwriters' fire pumps and pumps for water works, hydraulic elevators, boiler feed, railroads, mines, air compressors, etc.

Tested, approved and listed as standard by the National Underwriters' Laboratory.

Fisher Pump Governors are constructed in different types, handling up to 10,000 lbs. discharge pressure.

These governors are but a few of the complete Fisher Line. Our extensive experience with pressure regulating problems enables us to satisfactorily fill your every want — for pump governors, reducing valves, steam traps, float valves, etc.

Write for our interesting book,
"POWER PLANT SPECIALTIES."

MACLEAN STOKERS

There's a Correct Way to Fire Your Furnace

to get the best results from every pound of fuel used, and that is by the method exemplified in the **MacLean Underfeed Stoker** which regulates both the supply of coal and air. The result is a large saving of coal because of complete combustion. The **MacLean Stoker** saves labor and needs little attention, meeting varying demands for steam automatically.

We will gladly estimate what the MacLean Stoker could save in your plant.

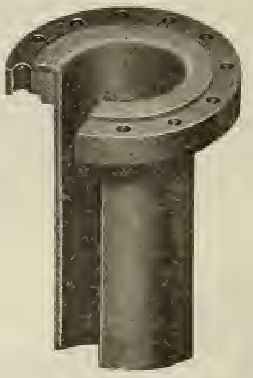
P♔H FLANGED PIPE JOINTS

SCREWED



P.H. LAP

P♔H LAP FLANGES, for any service, have proven to be the best yet designed, and they have many advantages over other styles. The pipe is not weakened by cutting into the wall as when using screwed flanges. The gasket bears on the face of the lap and absolutely prevents leakage through the bore of the flange. The hub of the flange is bored slightly larger than the outside diameter of the pipe so that the flange will swivel readily and accommodate itself to any slight variation in the position of the bolt holes, an advantage which is obvious to the fitter and eliminates torsional strains in attaching.

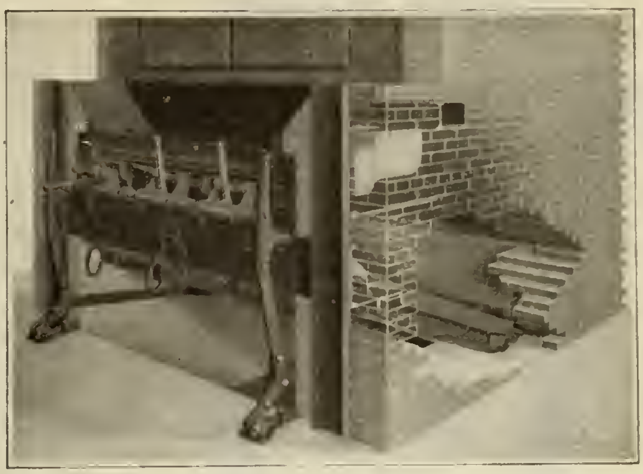
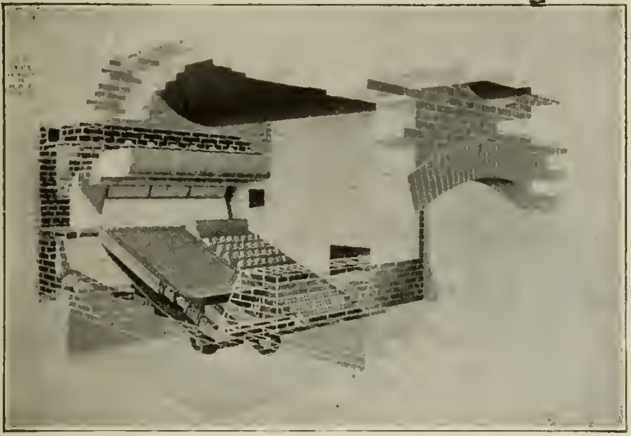
Type M.L. as applied to H.R.T. Boilers





The COKAL HOPPER-FEED STOKER

—for the plant that puts service ahead of "frills"—

THE CoKal Stoker has been installed in hundreds of prominent plants, not because it costs less but because the management was convinced that a stoker costing twice as much could accomplish no more.

These plants were willing to pay any amount for stoker service—but not one cent for frills! They wanted an "automatic" stoker, until they found that the CoKal, although not called automatic, did exactly what "automatic" stokers do. Then they refused to pay a premium for the word "automatic." If you want a full-fledged mechanical stoker—and won't become prejudiced because its price is much lower as a result of eliminating costly frills—then you will be interested in the new CoKal Hopper-Feed type.

How the fuel is mechanically fed and distributed is explained by the illustrations. Half swings of the long levers distribute the coal lengthwise and sidewise, filling up holes in the fuel bed and insuring even burning. A few swings of the short levers operating the feeder blocks force the fuel onto the stoker. Little if any more labor is required than is demanded by an automatic stoker—and the power drive of the automatic type, with its many expensive auxiliaries, is eliminated, permitting a far lower first cost. The "Coke-All" method of combustion means maximum fuel economy. Extreme simplicity insures reduced maintenance cost. Boiler capacity is greatly increased. Hand cleaning of fire is eliminated. No stoker is more responsive to load demands. Heavy peak loads are easily met.

Get the whole story of mechanical stoker service at hand stoker cost. Ask for booklet to-day.

The Dunham Return Pump
Type R. L. P.

HANDLING CONDENSATE
WITH THE
DUNHAM RETURN PUMP

This Dunham Return Pump is designed to automatically pump condensate from heating systems, or process work, back to boiler, heater, hot well or other storage. It is an automatic, electric driven, centrifugal pump, stopped and started from a float switch.

The waste of condensate from heating systems where returns are below the boiler water line can be entirely eliminated by the use of the Dunham Return Pump. The condensation from the heating system is returned to the boiler as it accumulates, resulting in improved heating and a saving of fuel.

Dunham Return Pumps are absolutely automatic in action and operate without attention, day or night. There are none of the difficulties caused by low pressure steam pumps when fires are banked for the night.

Full particulars will be sent upon request.

The New Mount Royal Hotel is one of many Canadian installations of

The Taylor Stoker

That this new and up-to-the-minute hotel should be Taylor Stokered is not surprising for gradually the Taylor Stoker is becoming recognized as the safest investment where steaming capacity with absolute reliability is imperative.

Adaptability, flexibility, ease of operation and upkeep and economy of fuel and space are other features that are causing discerning engineers to specify Taylor Stokers.

Among our many other Canadian installations are the following:

Atlantic Sugar Ref. Co.,	4000	RBHP	Ford Motor Co.	3400	RBHP
Bathurst P. & P. Co.	1000	"	Goodyear T. & R. Co.	2100	"
Brunner Mond Co.	3600	"	Montreal L., H. & P. Co.	6000	"
Dominion Coal Co.	2000	"	Proctor & Gamble Co.	2600	"
Dominion I. & S. Co.	2800	"	Public Service Corp.	1200	"
Dominion P. & T. Co.	6600	"	Riordon Co., Ltd.	5700	"

St. Maurice Paper Co. 600 RBHP

If you are not entirely familiar with the features of the Taylor Stoker that make it a most profitable investment in any boiler room we will be pleased to furnish full details upon request.

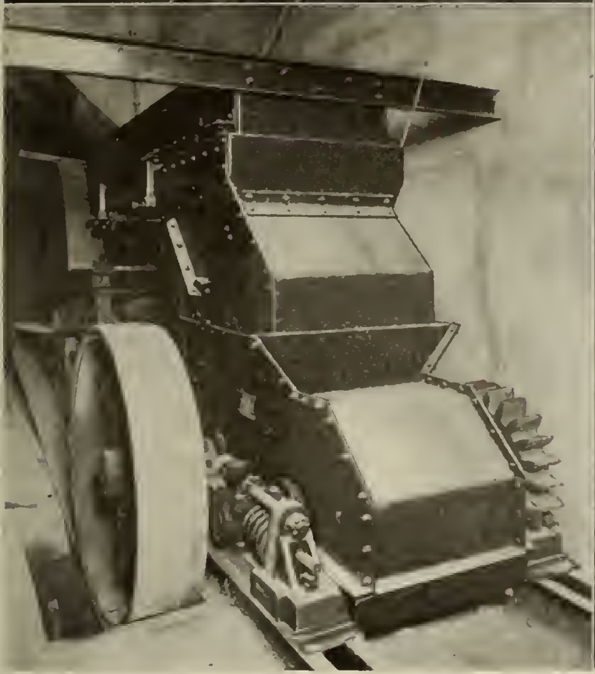
We will help you solve any practical pump problem. WRITE US.

PEACOCK BROTHERS LIMITED

MONTREAL



MOUNT ROYAL HOTEL IS LINK-BELT EQUIPPED

The Mount Royal Hotel can point with pride to the modern and efficient method of handling coal and ashes in their boiler house. Both the coal and ashes are handled by Peck Carriers—a sturdy, dependable machine which has been adopted by many of the foremost power plants of North America.

The choice of Link-Belt equipment was in direct keeping with the Mount Royal's ideas of power plant efficiency and economy of operation.

The illustrations show views of the Peck Carrier, upper and lower runs, and the Link-Belt coal crusher.

Let us send you in convenient form, further information on the efficient handling of coal and ashes. Write for Book No. 220

Artistic, Fire-Resisting Buildings of Concrete

The new Mount Royal Hotel and the Canada Cement Company Building add to the architectural achievements of Canada's greatest city.

It is particularly gratifying to have Concrete and Concrete products aid in this accomplishment. The facing and stone trim, manufactured by the Canadian Benedict Stone Co., Ltd., in Montreal, is used on the Mount Royal Hotel. The same stone is used on the Canada Cement Company Building.

This manufactured stone is reasonable in cost as well as pleasing in appearance. It is being used in many of the important structures now under construction in Ontario and Quebec.

The foundation and floors of the new hotel are reinforced concrete and the Canada Cement Company Building is Concrete throughout.

These two beautiful structures are fire-resisting—a most important consideration in a hotel and office building. Our confidence in the fire resisting qualities of the Canada Cement Company Building is evinced by our decision to carry no insurance whatsoever on the building.

We have literature on the possibilities of Concrete in office buildings.

We shall gladly mail copies free to anyone interested.

View showing Frick Uniflow Engine Driven Ammonia Compressors in Main Refrigerating Plant of the Mount Royal Hotel

A unique feature of this installation is that the ammonia compressors are driven by Frick Uniflow Poppet Valve Steam Engines—the first to be installed in Canada. The Uniflow principle reduces cylinder condensation to a minimum while the poppet valves permit operation at high speed and with high temperature steam, thus effecting an economy never before reached with steam engines.

In addition to the main plant, a separate automatically controlled Frick refrigerating unit is installed on the 11th floor of the hotel to take care of the requirements of the kitchen, dining room refrigerator, etc., in connection with the convention halls and grand ball room.

The world wide reputation of Frick ice-making and refrigerating machinery and the satisfactory service it is giving everywhere made "Frick" the natural choice for the Mount Royal Hotel.

Manufacturers of Ice Machinery Superior since 1882

MOUNT ROYAL HOTEL, Montreal

In the Power Plant of this new hotel which is described in a leading article in this issue, Bailey Meters are used for the measurement of steam generated and distributed.

Each boiler is equipped with a Bailey Boiler Meter that indicates, records and integrates Steam Flow, records Air Flow, Flue Gas Temperature and Steam Pressure on a single chart.

The total feed water is measured by a meter that records and integrates the Flow of Water and records Water Temperature. Meters to record and integrate Steam Flow are used on the steam lines to the kitchen and the laundry.

With the whole story on the chart there is no guess work about the results being obtained.

POWER EQUIPMENT OF THE EMPIRE'S LARGEST HOTEL

Mount Royal Hotel Costing $7,000,000 Has Interesting Ventilating, Heating and Refrigerating Installations

By J. G. Soucy

DURING the last 10 years there has been felt a growing need for additional hotel accommodation in Montreal, designed not only to meet the needs of the travelling men and the ever-increasing number of tourists, but to meet the growing demand for better and larger accommodation for general conferences and international conventions. The Mount Royal, with its many beautiful and convenient appointments, was the logical outcome of such an unmistakable demand. The hotel is under the direction of the United Hotels Company of America.

Much could be written about the commercial importance of this enterprise from both a national and an international aspect, but the outstanding purpose of this article is to describe features of the power plant equipment, which are of particular interest to our readers.

The hotel has a most convenient location, just one block north of the busy corner of St. Catherine and Peel Sts. The main entrance is on the east side of Peel St. It is in the heart of Montreal's busy shopping district and convenient to all theatres, railroad depots and boat landings.

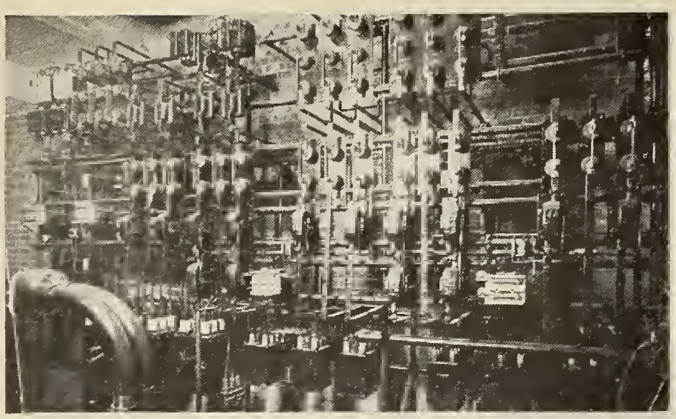
Just north of it is Mount Royal and to the south flows the majestic St. Lawrence, with its important shipping facilities. To the east are to be seen large industrial centres, here and there studded with churches and office buildings. A little to the south, is the great financial centre, while to the west are fine residential districts.

The Finished Undertaking and General Plan

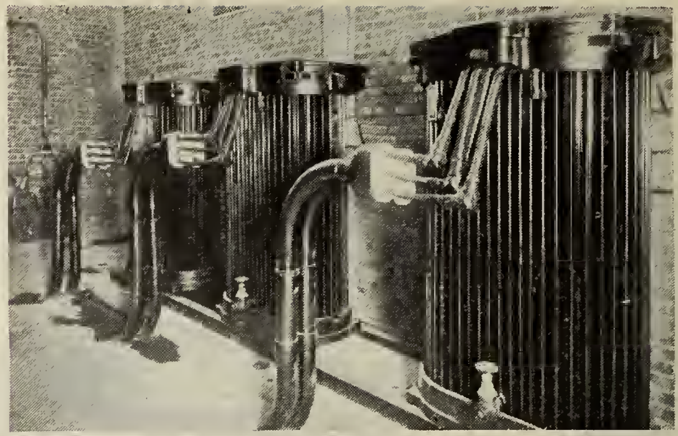
Some idea of the magnitude of the undertaking may be gained from the fact that the building is 130 feet high, occupies a space 306 ft. long by 227 ft. wide, or an area of 70,000 sq. ft., weighs approximately 150,000 tons; it has cost more than $7,000,000 to build and required over one year to complete. There have been more than 1,500 men employed directly on the site, which included laborers, mechanics and artists; besides a large staff of expert architects, accountants, draftsmen, mechanical and electrical engineers, superintendents, supervisors and inspectors.

Away from the site, hundreds of workmen were provided employment in quarries and forests, brick-kilns, cement works and saw-mills, steel works, foundries, and machine shops; various kinds of factories and warehouses, in stores and studios, all for the purpose of providing structural beauty and supplying necessary comfort to the travelling public.

Besides being one of the finest hotel buildings in Canada from an architectural standpoint, it is fireproof throughout. It is the largest hotel in the British Empire, if not in the world. It has 1,100 rooms with bath and toilet conveniences, a large, commodious vestibule and main corridor, as well as two large convention halls. One of these halls, known as the grand ball room, has a seating capacity of 2,000 and the other of 1,200; also, there are several private dining rooms besides the large main dining room.



High Tension Bus-Bars.



High Tension Transformers.

The ground floor is occupied by stores and there are 10 stories above for the accommodation of guests, the tenth floor being used for banquet and convention halls. In the "Pent House" above the roof, additional separate and complete units for ventilation, refrigeration, etc., are installed. The ground floor further contains the most complete and up-to-date kitchen bake ovens, cold storage, refrigerators and general storage spaces. Below is the basement which contains the most modern laundry equipment, refrigerating and ice-making machinery, also power plant for heating, lighting, ventilation, steam-driven refrigerating apparatus, steam-driven electrical generating sets and switchboards, also water softening and filtering systems.

Architecture—Georgian and Italian Renaissance

The exterior architecture of the building is "Georgian," and the materials used were well selected for the style so adopted. The principal materials used consist of Stanstead granite and Canadian Benedict buff stone also Hocking Valley and Upper Kittanic light buff brick. The interior design is generally what is known as "Italian Renaissance."

The "Georgian" is a neo-classic style of architecture which flourished in England from 1715 to 1800, during the reign of the Georges. It is a combination of the Italian and the Palladian styles, divested of excessive ornamentation.

The architects were Ross & MacDonald, 1 Belmont Place, Montreal. The general contractors were Thompson, Starrett Company, Ltd., Drummond Building, Montreal, A. G. Moulton, vice-president and general manager.

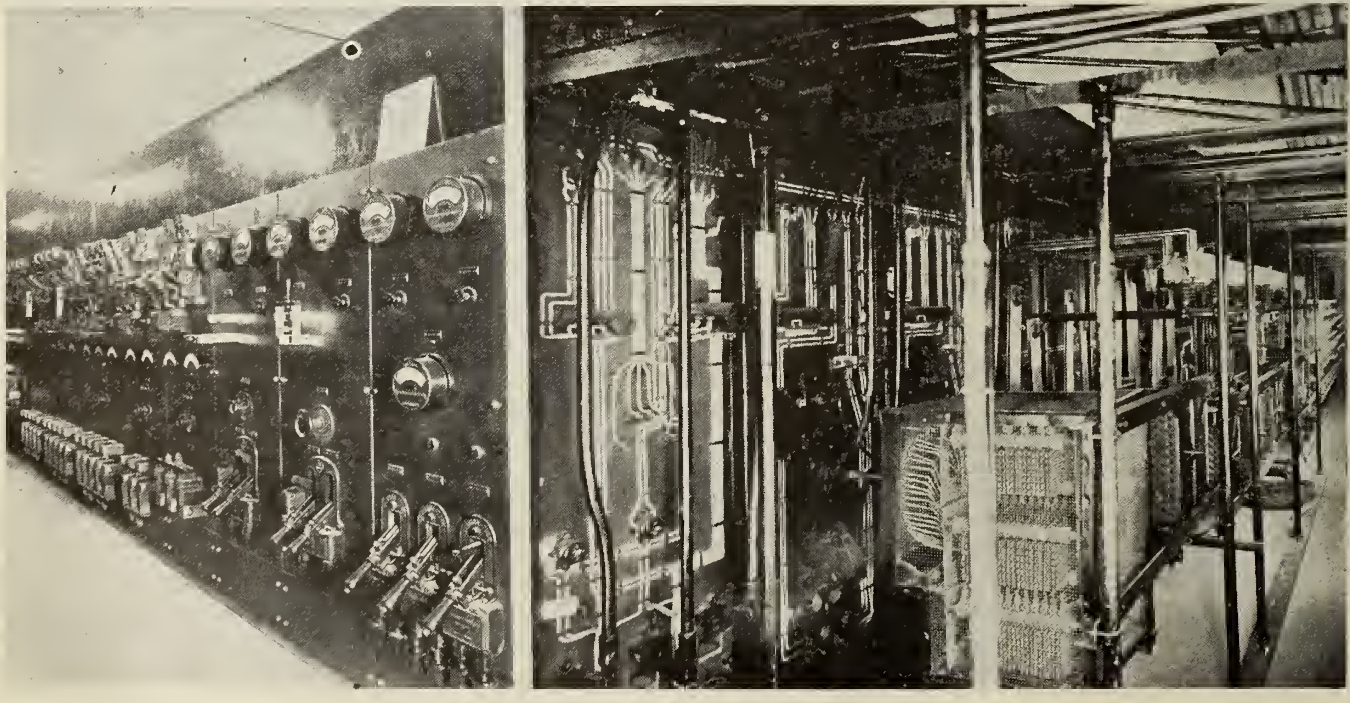
Power Plant and Equipment

Some idea of the amount of power plant equipment required to meet the needs of this hotel may be gained from the fact that there is about 8,000,000 cubic feet of space to be lighted, heated and ventilated; besides the fact that the hotel may be called upon to entertain, feed and otherwise look after the personal comforts of four to five thousand people at any time, and provide sleeping quarters, fully equipped with bath, toilet, etc., for 1,100 to 2,500 persons.

The basement and sub-basements are probably better ventilated than the average hotel or private home, and the whole arrangement is so complete in every detail that nearly all the wants or needs of its patrons can be supplied within the confines of this building.

Ample space and capacity is provided for store-rooms, kitchen bake ovens, laundries, work-shops, ice-making, refrigerating and cold storage; also an abundant supply of fresh air and cold drinking water to each room.

The drinking water is supplied from an artesian well, 10 inches in diameter and 830 feet deep, (875 feet below street level). The well penetrates and gets its supply from two veins, located respectively at levels of 362 and 830 feet below the basement floor. The supply would seem ample, as a test made showed a capacity flow of 7,200 gallons per hour of pure water at 42°F. The water is elevated from the 91 foot level



Main Switch Board Showing Equipment on Front and Back.

by means of an Ingersoll-Rand A No. 7 Type V.A. Imperial air lift or ejector, and the air compressors used will be described later in this article. The water, after passing through suitable filters, is circulated through brine-cooled coils which reduces its temperature to that desired for human consumption. The brass pipes through which it is circulated are all covered with heavy cork insulation made by Armstrong Cork Company, Montreal. The surplus water goes into the two large storage tanks on the roof used for general supply.

Coal Handling Equipment

The coal is provided in carload lots, or unloaded from boats at Windmill Point, and hauled in 5 ton trucks to the site where each load is carefully weighed on a Canadian Fairbanks-Morse platform scale after which it is dumped into one of the four manhole openings in the sidewalk, all of which are directly over the large coal storage bunker space provided. The storage capacity of the main coal bunker is 500 tons, and the general dimensions are 30 x 100 x 30 feet high.

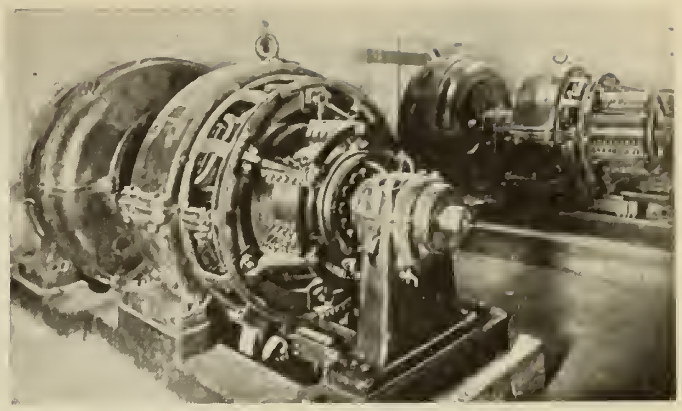
Elevator Controls "Pent House."

Coal in storage is reclaimed by means of openings in the floor leading to hand controlled loading or feeding chutes which discharge into the bottom or horizontal section of a Canadian Link Belt bucket type of "Peck Carrier." This conveyor has a capacity for reclaiming coal at the rate of 20 tons per hour.

Gauge Board in "Chef's" Room.

Run-of-mine coal is dumped into a large steel hopper over the crusher section of the conveyor, while stock coal is unloaded over any one of the four other openings and falls directly into the main storage space provided in front of the boiler. One of the special features of the conveyor system is, that all three motors used are connected in series so that, in case of a break-down, plugging is avoided as the crusher and feeder motors would be stopped automatically, in case the conveyor section is not running.

The electric motors used in connection with the coal conveying apparatus are all of the 220 volt, d. c. General Electric shunt wound type. They vary in size as follows: The feeder motor is 5 h.p., the crusher motor is 15 h.p. and the conveyor driving motor is 5 h.p.

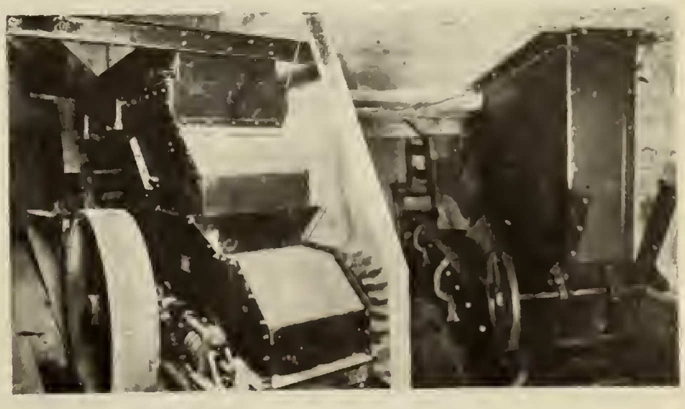


Motor Generator Sets.

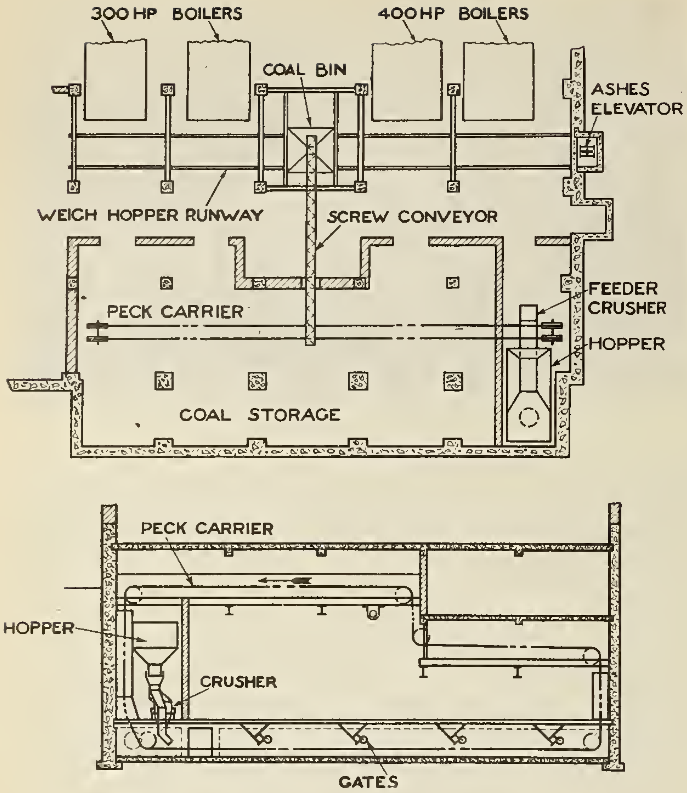
Coal is elevated about 25 feet from the coal-tunnel where it is discharged into a cross-conveyor of the helicoid or "screw type," which empties into an elevated steel bunker of 6-ton capacity, made by the Dominion Bridge Company. The coal from this bunker is discharged into a travelling (combined hopper and weigher) "larry" of 1,000 lbs. capacity, with scales made by the Standard Supply Co. of Pittsburg, Pa., through the Canadian Link Belt Company. The "larry" illustrated here is moved along from one boiler to another by hand and the

VISION — THEN AND NOW

INDOMITABLE faith and wonderful vision are terms that have been frequently used in descriptions of the New Mount Royal Hotel. It may be interesting to recall that faith and vision had much to do with the founding of Ville Marie de Montreal in 1641—1642. The romantic story had its beginning in Old France where one, Jerome de la Dauversiere, desirous of launching some plan whereby the red men of Canada might be won over to Christianity, claimed to have been told by an angel that the first step toward this object would be the setting up of a mission on the Island of Montreal. From this inspiration developed the expedition of Maisonneuve who, with a company of fifty, landed on the site of the future metropolis some two hundred and eighty years ago. The spot had been visited by Cartier one hundred years before, but there had been no subsequent settlement. Not long did the Iroquois permit the newcomers to remain unmolested and the story of Maisonneuve's heroic defence is one of the finest epics of early days in this country. His memory has been perpetuated in graceful form by the statue in Place d'Armes Square. It is from this spot that the eastern metropolis has radiated with characteristic faith, courage, perseverance. Maisonneuve and his little company might easily lose themselves in the splendid structure that has just been completed. It is not the only instance in Canadian history where the visit of a missioner has formed the foundation for modern perspective and enterprise.



Coal Crusher and Loading Chutes.



Plan and elevation of coal bunkers and conveyor.

coal is discharged or unloaded, as required, into the different stoker hoppers—the coal being automatically fed from the hopper to the stoker. Plan view of the coal conveying and ash handling system is shown herewith.

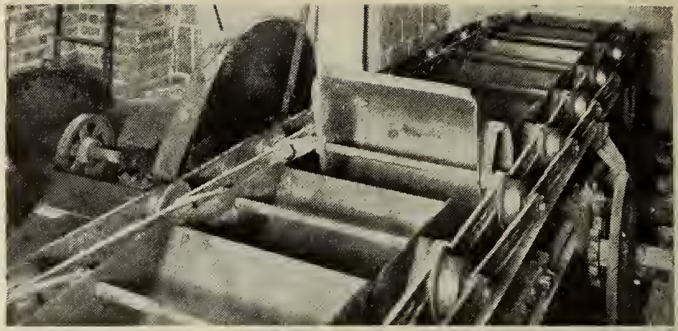
The power plant proper consists of 4 Robb water tube boilers, 2 steam-driven generators, 2 steam-driven feed pumps, 2 steam-driven vacuum pumps, 2 steam-driven supply pumps, 2 air compressors (one steam-driven and one motor driven); 2 steam-driven refrigerating machines, 2 motor generator sets and large motor-driven ventilating fans, motor-driven elevator hoists and numerous smaller electric driven circulating and sump pumps. The boiler and engine room floors are approximately 30 feet below the street level and the main portion of the power plant is located in the north-east portion of the sub-basement or near the corner of Burnside and Medcalf Streets.

About 10 feet below the boiler room floor is the smoke tunnel, ash pit tunnel and coal conveyor tunnel. The bottom horizontal section of the coal conveyor is about 100 feet long.

Boiler Room Equipment

There are installed in the boiler room 4 Robb water tube boilers. Two of the boilers are of 400 h.p. capacity each and two others are of 300 h.p. each, making a total of 1,400 h.p. installed. The boilers are of the double cross-drum type and designed to carry 160 lbs. pressure.

They are not equipped with regular super-heater units, although there has been provided a special superheating feature, the top rows of tubes being so designed that the equalizing steam passing through them is exposed to the hot combustion gasses in the first stage or pass. The boiler ratings are based on the usual formula of 10 sq. ft. of heating surface per h.p. The boilers are supported upon steel columns, made by the Dominion Bridge Co., and erected by the Engineering Sales & Service Company, Montreal. The boilers are equipped with Turner baffles, which together with the brick settings, and furnace linings, were installed by Mander & Lucas. The furnaces are lined with Glenboig fire brick and the back passes with Lumber City fire brick. The boilers are all equipped with stokers, furnished by the Taylor Stoker Company of Canada, Limited. Two of the stokers have 3 retorts each and the two others 4 retorts each, there being one retort per 100 h.p. demand. Each retort is provided with 17 tuyeres. The stokers are driven by 4 12½ h.p. vertical steam engines. The stokers are intended to burn either anthracite screenings or slack (bituminous) coal or a mixture of both. The overload capacity of these stokers is 200% of rating.

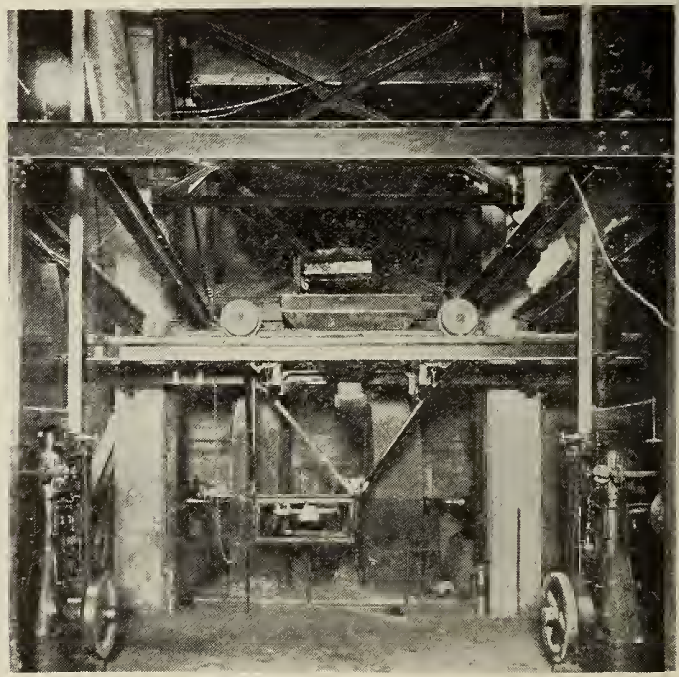


Coal Conveyor.

The compressor plant is described as comprising an Ingersoll-Rand class ER-1 single stage straight line short belt motor driven air compressor equipped with the latest type of I-R plate valves, permitting higher overall efficiency than any similar equipment yet produced. This unit is used for regular operation, and for standby purposes, an Ingersoll-Rand class FR-1 I-R single stage straight line steam driven compressor is installed. This machine is also equipped with the latest type of plate valves and I-R balanced piston steam valve. An unique feature of the compressor or plant, which is strictly up-to-date in all respects, is that special precautions were made to prevent the noise of operation from travelling throughout the building.

The advantages of this plant are extreme simplicity and reliability, large capacity, limited only by the source of supply, low maintenance cost and great flexibility. A further advantage is that the water is very thoroughly aerated by the amalgamation of the air and water passing through the discharge pipe. The extensive aeration to which the water is subjected and the natural filtration due to the subterranean sources of supply produce a pure undefiled water which is particularly adapted to hotels, breweries, bottling works and municipalities.

The advantages of the particular type of pump installed are: Realization in the most efficient manner of all of the advantages to be gained by use of an air lift pump. In practice the air in the Type "VA" Pump is divided into fine streams



Coal Bunker and "Larry" in Boiler Room.

which is an essential requirement in air lift pump efficiency.

A proper amount of back pressure is held in the pump and prevents sudden rush of air due to the coalescence of bubbles and lightening of the discharge column. There are no moving parts whatever. The foot piece offers a smooth, unobstructed entrance and discharge chamber. There are no nozzles or obstructions.

It is impossible to prevent scale and dirt passing down the air lines into the pumps, consequently provision must be made to eliminate any such trouble with certainty. In the class "VA" pump any foreign material which may come down the air pipe falls through the unobstructed openings between the outside casing and the inner tube.

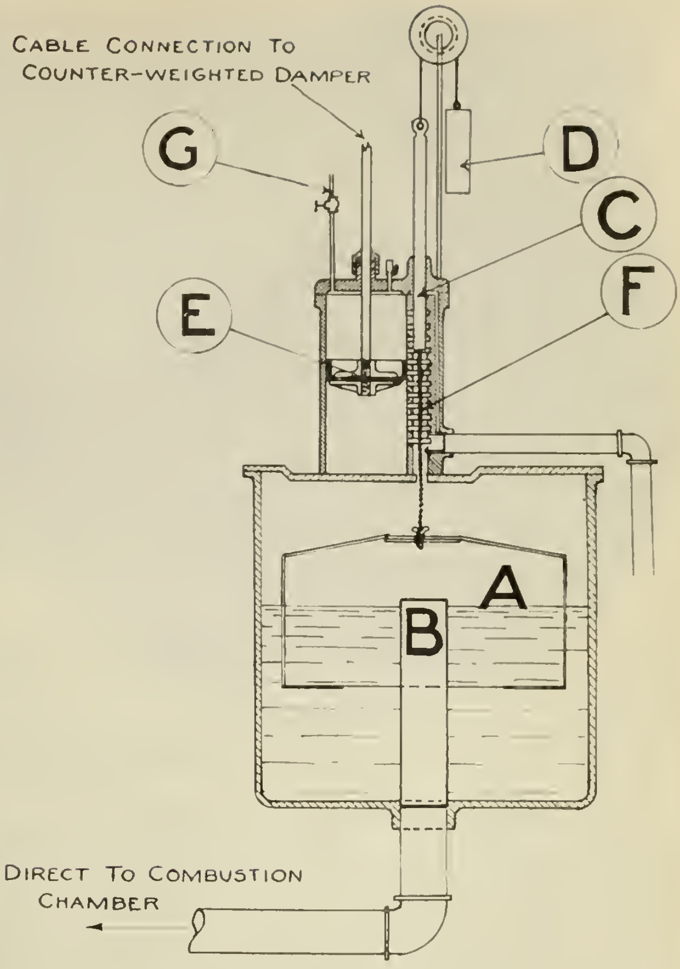
This regulator made by the Craig Regulator Company of Canada is a very simple device, and its control of the damper is actuated by fluctuation in the draft over the fire, with the result that if the draft becomes excessive beyond the point for which the regulator is set, the damper is closed sufficiently to bring it back to normal, and vice versa.

A glance at the line drawing will make the following description very clear. The 2 in. pipe B opens directly into the combustion chamber at one end, and as shown under the gasometer float A in the regulator itself, the gasometer float is connected through a chain F to a plunger C which moves vertically in a multi-port valve opening and closing the ports with the movement of A. The piston E is in a cylinder off which the multi-ports of the valve just mentioned open. This cylinder is fed by water from a pipe G from city water supply, which is controlled by a needle valve. The counterweight D balances the plunger C, chain F, and gasometer float A, and any extra weight in this counterweight takes care of the position of the damper to give the required draft.

The action, briefly, is as follows: Any extra suction at D exerts a downward pull on A, and consequent downward movement of C, closing off the ports in the multi-port valve. Immediately the pressure in the piston chamber above E is built up through the inflow of water at G, causing a downward movement of the piston and a closing of the damper which will reduce the suction. It should be noted that the piston E by the closing action of the damper, will be comparatively slow, as the inflow of water through G is cut down to a minimum by the needle valve. On the other hand, when the reverse action takes place, the plunger C rises and opens as many ports in the valve as the decreased draft condition dictates, allowing a quick rise of the piston E, and the consequent quick opening of the damper.

Coal "Larry" Supplying Stoker.

Steam Engine Driving Stoker.



Damper Regulator.

Forced (Balanced) Draft System

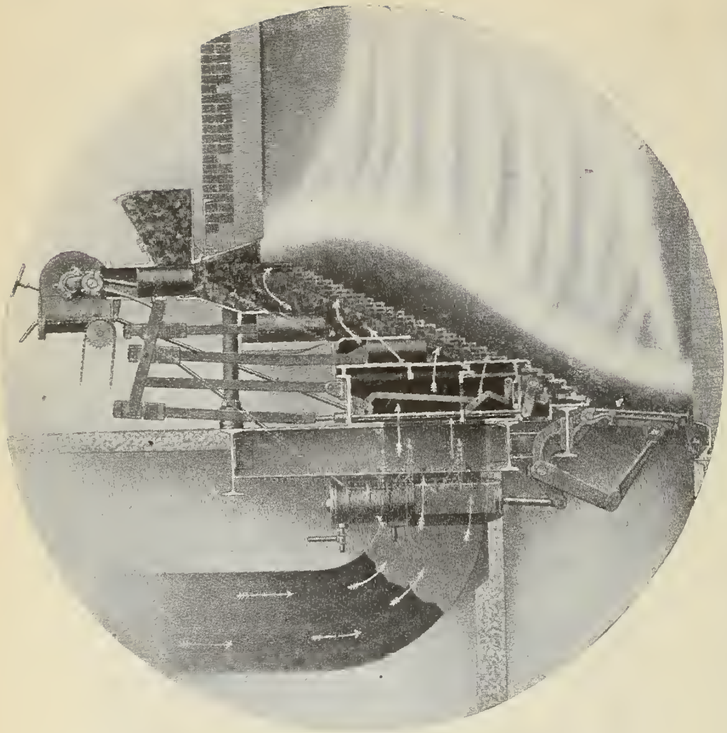
The forced draft equipment consists of 2 (Keith) Sheldon's, Ltd., fans supplied by Ross G. Greig, of Montreal. The fans are driven by two 25 h.p. vertical steam engines, by the Troy Engine Foundry & Machinery Company, of Troy, Pa. The forced draft fans and engines are set in an offset directly in front of the boilers. These fans are used in combination with a Craig damper regulator attached to each boiler which results in a balanced draft being maintained automatically.

An unusual feature encountered here is the "down-draft" direction of the gasses or products of combustion from the last pass to a smoke tunnel below and thence up to a round (brick-lined) steel stack or chimney.

The smoke stack is 7 ft. 6 in. in diameter and 182 feet high above the boiler room floor. It was built and erected by the Dominion Bridge Company. It extends 30 feet above the main roof and this is the only portion of the stack which has not been lined.

Soot blowers or cleaners—Each boiler is equipped with six units of Diamond soot blowers, valve-in-head type, supplied by the Cleaton Company, Montreal.

The water columns are all equipped with high and low water alarms. The safety valves consist of two 4" "Pop" or



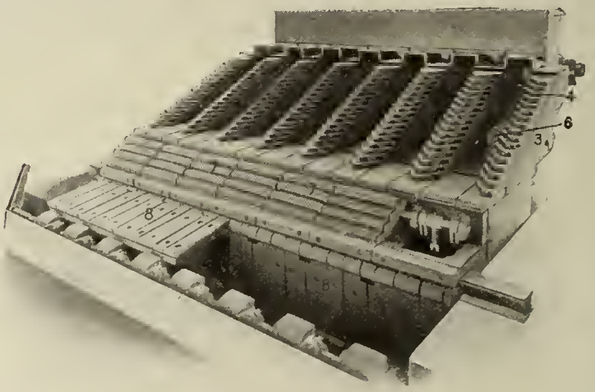
Sectional view of stoker, showing series of coal feeding plungers.

spring leaded type of valve supplied by T. McAvity & Sons.

Feed water regulators—Each boiler is equipped with Copes feed water regulators, made by the Northern Equipment Company, and supplied by Peacock Bros., Montreal. They automatically regulate the flow of feed water to meet requirements.

Main stop and non-return valves—There are four 6 "D" main stop non-return Lunkenheimer steam valves, supplied by the Garth Company, Montreal; also Lunkenheimer stop and check valves in the feed water lines.

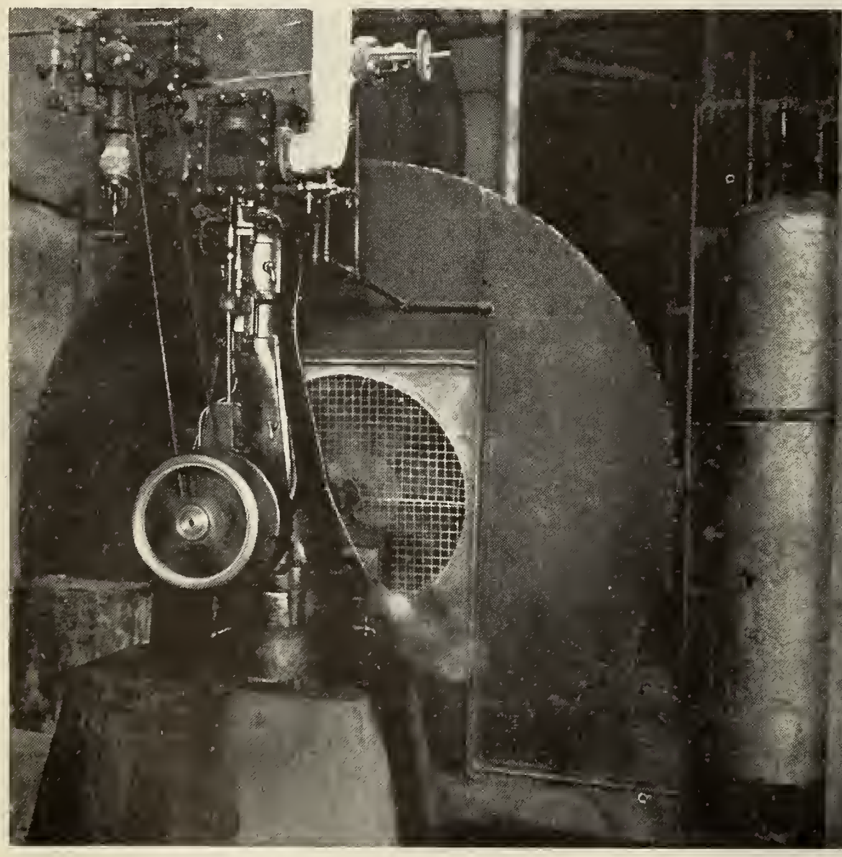
Blow-down valves—There are two sets of blow-down valves to each boiler, one is of the type of everlasting B. O. valve; and the other consists of Lunkenheimer gate valves. The blow-down discharges into a large B. O. or expansion tank, made by Darling Bros., Montreal. The drains from the above tank are led into a sump-pit or tank below the boiler room floor, and a set of ejector pumps remove the waste water to the main sump-pit. The steam gauges, made by the Foxboro Company, Foxboro, Mass., and were supplied by Peacock Bros., of Montreal.



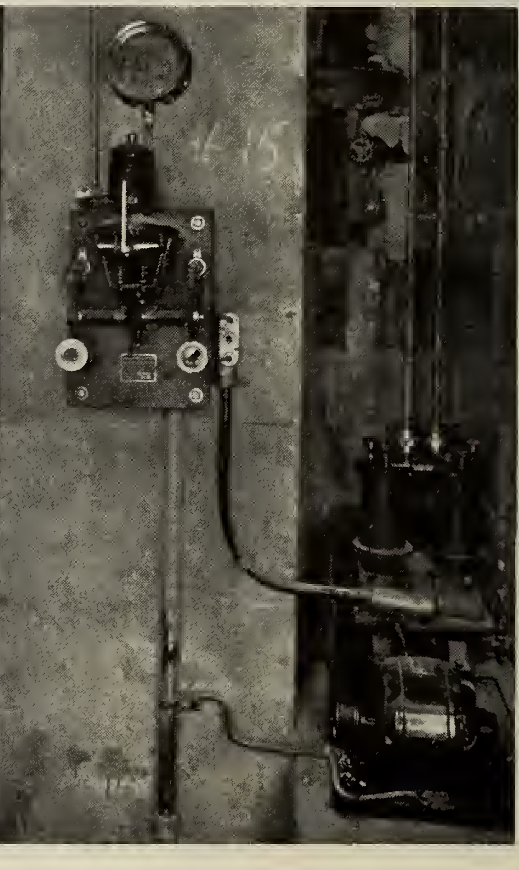
Inside view of furnace showing multiple retorts of stoker.

Boiler meters.—Each boiler is equipped with a Bailey boiler meter type 26, class 56, which indicates and records the air flow, steam flow and the flue gas temperature, also the draft in the fire box; in addition to the above there is an integrating feature which totalizes the flow of steam for any desired period.

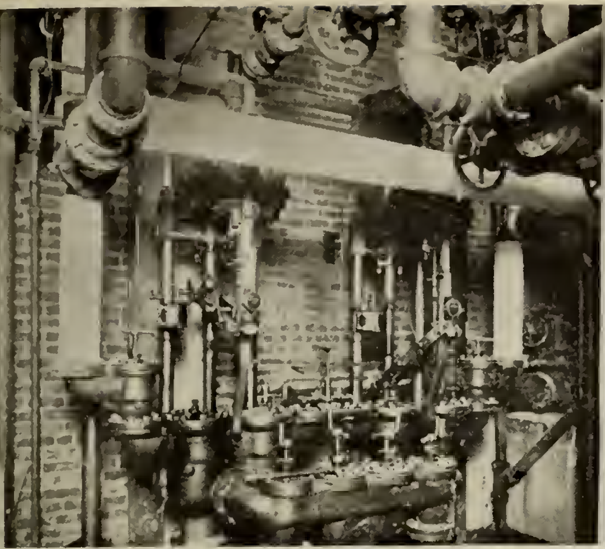
Steam flow meters.—There are two Bailey steam flow meters, type C6, class 1, which indicate and record the flow



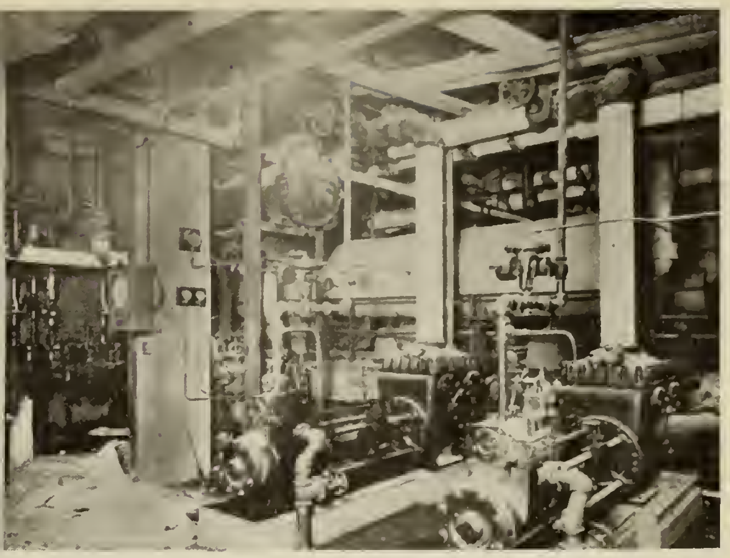
Engine and Fan For Forced Draft.



Johnson Regulator and Air Compressor.

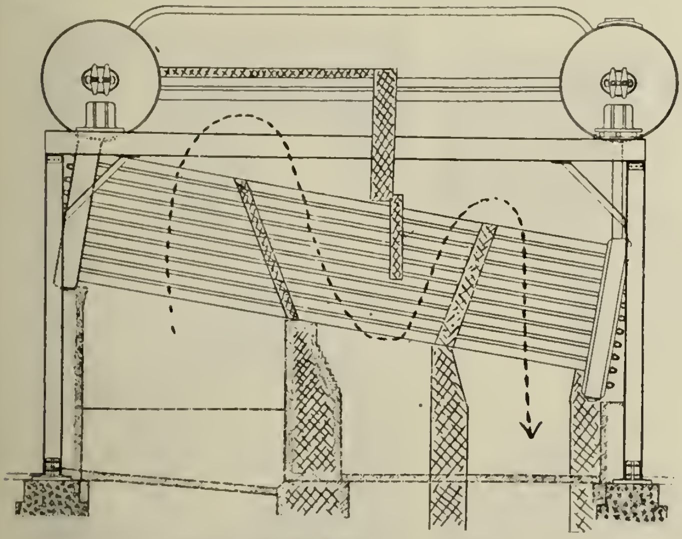


Twin Feed Pumps.



Corner of Pump Room.

of steam other than that used for power and heating purposes. They are also equipped with an integrating feature for totalizing the amount used for any desired period. One of them is used to meter the steam used in the kitchen, and the other to meter the steam used in the laundry. It is quite important that the steam used for power in summer and that used for heating in winter should be determined by similar instruments. In this way the amount of condensate going to the sewer could be determined and in such a large plant the corrective value of such information would prove valuable and result in a direct economy.



Special Baffling and Down Draft.

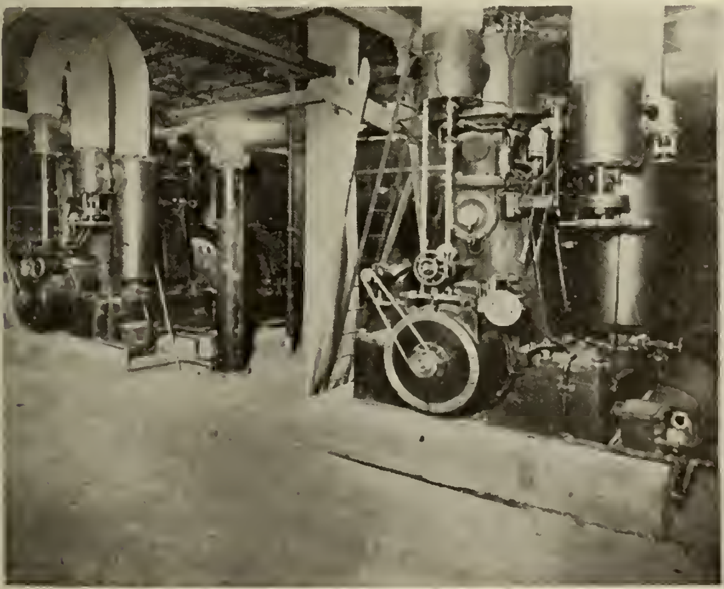
Steam and Hot Water Distribution

Steam branches from the boilers are all connected into a 10 in. main steam header or "log" from which an 8 in. loop provided steam for all the auxiliary steam pumps and engines located in the engine and fan room.

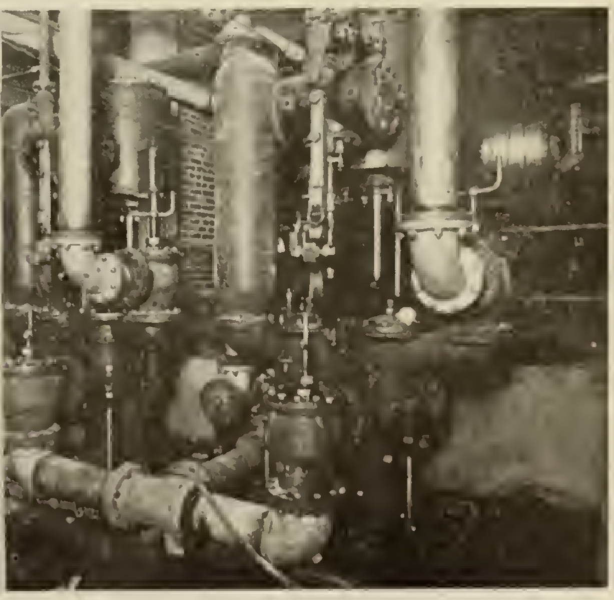
The steam is distributed first at 160 lbs. as above described, another line known as the high intermediate carries 80 lbs., another known as the low intermediate carries 40 lbs. and the low pressure from 2 to 3 lbs. is used for heating purposes entirely. All the steam piping from 5" up to 10" as well as all brass and iron pipe is of the Crane make, and all high pressure steam valves are of the Lunkenheimer make; Crane valves are used for low pressure steam heating.

Philip Carey—85 per cent. magnesia pipe covering was used by Wm. Rutherford & Sons for all tanks and steam pipes. The feed water control and check valves are Lunkenheimer make supplied by Garth & Co.

A Bailey feed water meter, type C2, class A, is used to indicate and record the flow of feed water to the boilers; the



Steam Driven Generator Sets.



Service and Fire Pumps.

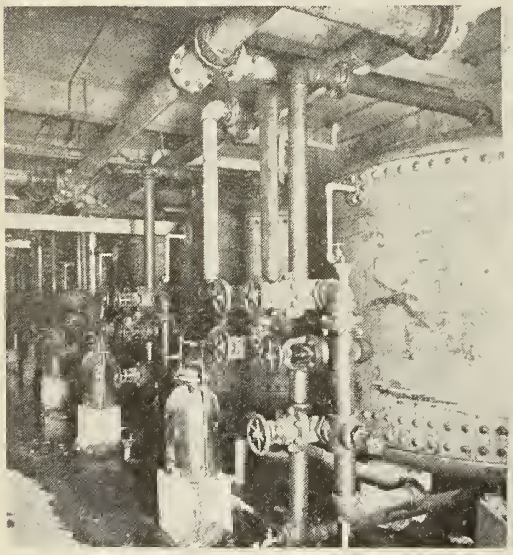
temperature of the feed water is also indicated and recorded; also this meter is equipped with a special integrating feature which totalizes the amount of feed water used for any desired period.

Feed water pumps.—The two 10½x8x24" steam driven, vertical direct acting, Weir feed water pumps, through Peacock Bros., are the latest design of the G. & J. Weir Pump Company. Their capacity is, in excess of that required, (200 lbs. head at a speed of 12 double strokes per minute), 5,930 imp. gallons each per hour. These pumps are equipped with Copes feed water pump regulators. There are two size 5 Blackburn & Smith Corp. feed water filters.

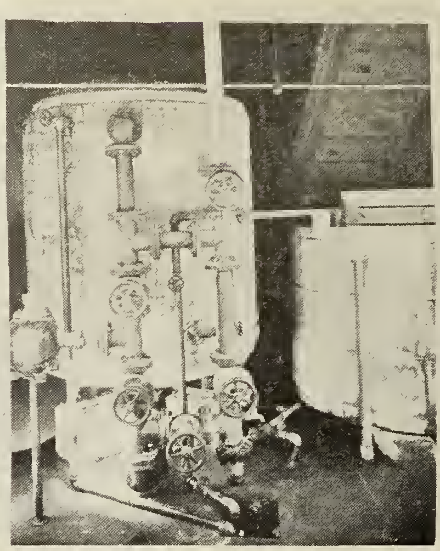
The feed water heater, illustrated here, has a capacity of 3,950 gallons per hour and is of the closed type. It is heated generally by exhaust steam and is equipped with a Powers automatic temperature regulator.

In the winter time there will be a large amount of condensate from the heating system returned to the hot well or feed water supply tank; and the make-up water is taken from the two large storage tanks upon the roof. Each storage tank has a capacity of 10,000 gallons of filtered water. Further provision has been made for supplying the boilers direct from the two city water service connections. There are in all five sources of feed water supply.

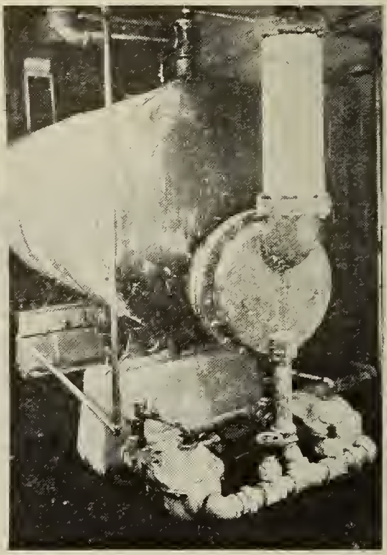
(1) High pressure city water direct to boilers at 135 lb.



Pressure Filters.



Water Softener.



H. W. Supply Tank.

(2) Filtered water from the service supply pumps at 150 lbs.

(3) Low pressure city water (60 lbs.) by feed pumps at 175 lbs.

(4) Hot water returns from the heating system by feed pumps at 175 lbs.

(5) Water from the artesian well, should an emergency require at 15 to 175 lbs.

City water connections—Provision has been made for two water connections, one from the high pressure service (Peel St.) at 135 lbs., and another from the low pressure (Burnside) at 60 lb. One very objectionable feature, an engineer will note here, is the use by the city of Montreal of left-handed stop valves. Such a practice should be discontinued at the earliest possible moment.

Pressure water filters—The 6-78" Refinite pressure filters shown here have a capacity each of 6,000 Imperial gals. on a basis of three gallons per square foot per minute. The hot water supply for wash basins, baths and shower baths, also kitchen and laundry, is provided for by five large cylindrical tanks, heated by exhaust steam. One of them is used exclusively for the laundry. They have a combined capacity of 19,000 gallons per hour.

Water softener and brine tank—The 60 inch water softener and brine tank by Refinite Co. of Canada has a guaranteed capacity of 46,000 Imperial gals. in 10 hours. The softened water is provided for use in the laundry.

General supply and fire pumps—The general water supply for the building, also emergency for fire purposes, is provided for by two steam driven 17x12x21 direct acting vertical Weir pumps. They were supplied by Peacock Bros., and have a capacity each of 24,000 Imperial gals. per hour at 170 lbs., (speed 26 double strokes per minute). Although the building is thoroughly fireproof, there will be at times considerable combustible material stored in it, so that arrangements were made that either one or both of these pumps could be used for fire purposes.

Vacuum pumps—The condensate from the heating system is handled by means of four Darling Bros. steam-driven vacuum pumps.

Condensate from the laundry during the summer is handled by Crane lifting traps.

An air compressor in a modern power plant is now considered indispensable. The Mount Royal is provided with two 12x10, made by the Canadian Ingersoll-Rand Company, Sherbrooke, Que. One is a steam driven unit and the other is motor driven by a Westinghouse electric motor.

Elaborate Electrical Installation

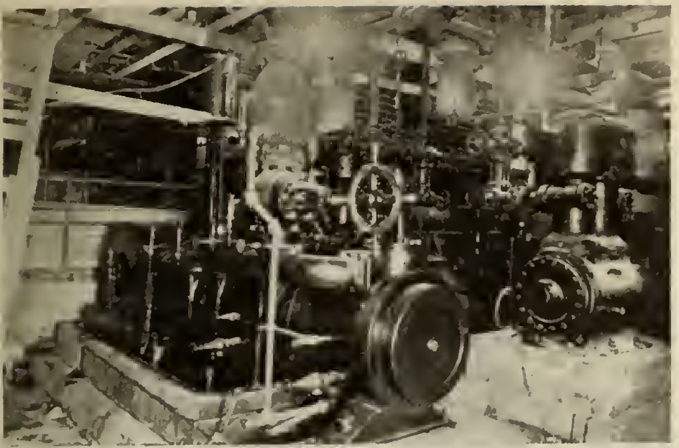
The electrical equipment consists of the following:

(a) 3-150 K.V.A. 2440 volt 60 cy. A.C. oil cooled transformers, by the Canadian Crocker Wheeler Company, St. Catharines, Ont.

(b) 2 sets of air-cooled transformers, by the Canadian Westinghouse Company, Hamilton, Ont.; one set of two is used to start the larger of the motor generator sets; the other set of two is used to start the smaller of the motor generator sets.

(c) Motor-generator sets, manufactured by the Canadian Westinghouse Co. The larger set consists of a synchronous-motor 435 h.p. 98.0 amps. at 2300 volts (a.c.) driving a 300 k.w. generator, 1305 amps. 230/115 volts at 630 r.p.m. The other set consists of a 2300 volts (a.c.) synchronous motor (290 h.p. 65.3 amps.) driving a 200 k.w. (D.C.) generator, 230/115 volts, at 630 r.p.m.

(d) 2 steam-driven electrical generators. The Bellis & Morcom steam engines have a capacity of 430 B.h.p. each normal load, and 25 per cent. overload when operating at 125 pounds pressure and exhaust against 3 pounds back pressure. They are direct connected to Canadian Westinghouse generator, 300 k.w., direct current three wire 125-250 volts. The generators are of Westinghouse make, each of 300 k.w. capacity 1305 amps. 230/115 volts (D.C.) at 375 r.p.m.



Frick Uniflow Engine and Ammonia Compressors.

(e) Electrical motors of various makes, which are described under the following headings:

Coal-conveying, ash-conveying, ventilating, exhaust and supply fans; elevators, passenger and freight; air compressors; refrigeration and brine circulation; sump pumps; laundry machinery; kitchen and service; elevator signal and safety; telephone system; pneumatic tube blower, miscellaneous electric fans, etc. All motors used generally are 60 cycle A.C. 230 volts. The motor load is approximately 300 h.p. The lighting load is 450 K.V.A.

The electrical distribution system was designed and installed by the Canadian Comstock Company, of Montreal and Toronto, under the supervision of Mr. McCrom. In general, alternating current 60 cy. 110 volts is used for lighting purposes, and direct current at 230 volts is used for all electric motors.

The main switchboard consists of 18 panels installed in the sub-basement just west of the engine and pump room. These control motor lighting and 2300 v. circuits.

The principal pieces of equipment by the Metropolitan Electric Co. on the front of the main switch board are: D.P.-D.T., D.P.-S.T., T.P.-D.T. and T.P.-S.T. knife switches; volt and ampere meters, by Weston Instrument Co.; 9 General Electric and 9 Westinghouse circuit breakers; 2 D.C. and 2 A.C. G. E. watt meters.

On the back of the main switch board are mounted the following: Westinghouse rheostats and 3 control levers for the Westinghouse type B 1 oil switches and 6 control levers for the F 11 oil switches and a bank of fuse blocks and cartridge fuses by the Metropolitan Electric Company, Long Island, N.Y. The fuses protect both lighting and motor circuits leaving the board.

Back in the transformer room are the high tension bus bars and supporting frames. On this rack is mounted additional equipment consisting of disconnecting switches and 4 G.E. and 14 Westinghouse current transformers. In addition there is an auxiliary 3 panel switchboard erected in the "Pent House" above the main roof, to control the power for the 6 passenger and 4 service elevators, also the lighting and ventilating fans used to supply the two large convention halls and ball rooms on the 10th floor.

Vacuum Pumps and Return Traps.

The equipment of the auxiliary switch board in the "Pent House" is as follows: 3 large panels, two of them having 5 circuit breakers on each, which control the current to 10 elevators and the third panel controls the circuits to the exhaust and supply fans used in connection with the direct heating; also a circuit to the automatic, electrically-operated refrigeration system. On the back of the third panel is mounted a bank of Metropolitan fuse blocks and cartridge fuses.

The board for controlling elevator signals, Norton door closers and interlocking door switches, designed and erected by H. Voss, superintendent for the Canadian Electric Equipment Company, Toronto, has proved of special interest. It is also located in the "Pent House."

Besides the main and auxiliary switch boards mentioned previously, there are many power and lighting distribution boxes located at different convenient places throughout the building. Some of them are equipped with the Hart magnetic control switches by the Devoe Electric Switch Company, Montreal. The wires for both lighting and motor circuits are all run in approved conduit and the 5,000 outlets made with approved outlet boxes, by Canadian General Electric Co. Five carloads of ½" to 4" Beaverduct were used.

Main Sump-Pumps and Fan Room.

Passenger and Freight Elevators

The purposes, sizes and capacities of the elevators (Otis-Fensom) vary as follows:

6 passenger of 2 to 1 traction type, cap. 2,500 lbs., speed 450 p.m.

1 employee's of 2 to 1 traction type, cap. 2,000 lbs., speed 200 p.m.

3 service of worm gear type, cap. 2,500 lbs., speed 400 p.m.

1 freight and service of worm gear type, cap. 3,500 lbs., speed 100 p.m.

1 freight of worm gear type, cap. 3.500 lbs., speed 350 p.m.

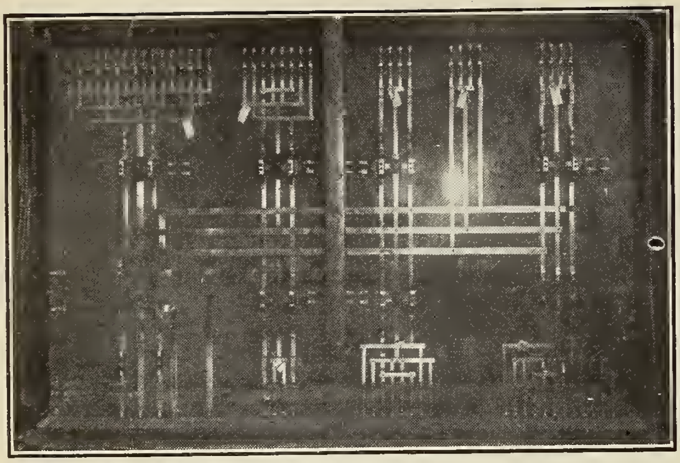
1 service of worm gear type, cap., 1,500 lbs., speed 50 p.m.

3 dumb waiters.

There are many small electric motors used in the kitchen, storerooms and service departments, which supply power to numerous new or up-to-date devices for increasing efficiency and economy.

Direct and Indirect Heating

Direct Heating—Some idea of the amount of radiation required may be gained from the fact that there is approximately 8,000,000 cubic feet of space to be heated, with a very large glass and outside wall exposure. There are installed 2,500 units of varying sizes of steam radiators by the Dominion Radiator Co. in the various bed, bath, reception, dining and special rooms, and the heating of them is controlled as required by modulation valves and thermostatic traps. It is estimated that from 60,000 to 63,000 square feet of radiation



Lighting Panel With Hart Magnetic Control.

was required to heat the building, including both the direct and indirect systems.

Indirect Heating—In connection with each fresh air supply fan, is a heating unit consisting of a bank of steam-heated pipe coils and in combination with it is an air washing or spraying system which controls and regulates the humidity or proper amount of moisture which the air should contain for health and comfort. The indirect radiation installed is approximately 11,000 square feet.

The heating equipment, the Kieley & Mueller steam pressure reducing valves, as well as Lunkenheimer valves constitute a Garth Co. installation. Low pressure steam valves were by Crane Company. All steam and water pressure gauges used, both indicating and recording, were of Foxboro make through Peacock Bros., Montreal. The condensate or hot water returns are handled in winter time by four Darling vacuum pumps. During the summer time the hot water returns are handled by Crane tilting and lifting traps.

WALTER T. ARMSTRONG,
Chief Designer, Ross & MacDonald.

Ventilation and Air Exhaust

There are a number of screened openings from which a fresh air supply is taken in at different parts of the building; however, there has been provided a cold air shaft direct from the roof which supplies fresh air to the main fan room situated in the sub-basement.

The fresh air supply to the main indirect heating is washed and carries the proper amount of moisture introduced before it is delivered to the lobby, main dining and special rooms. There are installed 10 fresh air supply fans and 14 air exhaust fans, all of which are of the Keith pattern, by Sheldons, Ltd., of Galt, Ont. They are driven by Westinghouse motors, which vary in capacity from 3 to 30 h.p. Auxiliary ventilation in the "Pent House" on roof is provided to take care of the grand ball or banquet room and convention halls on the 9th floor.

R. Miller, Superintendent of Building Construction, Thompson Starritt.

The hot air supplied to the various rooms passes through a "diagonal grill" or lattice-like face plate, by Tuttle & Bailey, Bridgeburg, Ont. The galvanized air-boxes or duct through which the hot air is supplied to the rooms and the used air is changed frequently or exhausted, are by Baxter & Webber, Montreal. Two hundred tons of Keystone galvanized iron was used to complete the amount of air duct required, and an average of 30 men have been employed constantly for several months making and erecting the work right on the job.

Ice-Making and Refrigeration

The main refrigerating and ice-making machines consist of what is said to be the first steam uniflow engines with poppet valves for both intake and exhaust, driving ammonia gas compressors. The complete outfit was manufactured and installed by the Frick Ice and Refrigerating Machine Company, Montreal. The engines are fly-wheel-governed and designed to operate at high speeds, ranging from 150 r.p.m. normal to 325 r.p.m. maximum. The vertical enclosed type of ammonia compressors are designed to compress the gas to 125 lbs. normal and 175 lbs. maximum. They have a capacity. each of 40 tons normal and 60 tons maximum. They were installed with a guaranteed capacity of 75 tons of ice per day.

The ammonia gas, after being compressed, is passed through a bank of condenser coils, where the temperature of the compressed gas is further reduced at least to 52 F., after which some of it passes either to a low temperature refrigerator or

Brine and Fresh Water Pumps.

the ice making room, where expansion takes place and the gas absorbs the heat from the substances to be frozen. Another portion of the compressed gas is expanded in coils about which the brine is circulated. The brine, after imparting its heat to the ammonia gas while it is expanding, becomes reduced in temperature and is circulated to the various tanks and refrigerators where only a moderately low temperature is desired. The drinking water supply for the guests is cooled by passing through a brine-cooled tank. The ammonia gas after expansion and absorption is drawn back into the compressors by the suction effect of the receding compressor pistons, and there compressed as previously described, thus completing the cycle.

In the ice-making room, which is about 30 feet square, there are about 500 large cans (8" x 16" x 32"), immersed in a tank full of a brine solution. The brine is circulated around and in between the immersed cans by means of two special brine agitators, driven by two 54 h.p. Reliance electric motors. The cans are filled with 100 lbs. of filtered water and when frozen are removed from the tank to the unloading and ice storage room; the cans are later returned to the tank filled with water and immersed again in the brine circulation. The brine in circulating comes into contact with submerged coils, where ammonia gas is continuously expanding and passing back to the compressor to be compressed again. The ice-making plant has a capacity of 250 blocks of ice every 24 hours, or 25,000 lbs. of ice. Adjoining the ice-making room is a large ice storage room commonly called the "ice house," which consists of a large room where the ice is piled up in tiers. This room is completely lined with 2" slabs of cork insulation, made by the Armstrong Cork and Insulation Company, Toronto and Montreal.

MOUNT ROYAL HOTEL MECHANICAL STAFF.

Front Row, left to right—W. J. Carmichael. Wm. Raeburn, senior shift engineers; S. J. Heenan, chief electrician; J. A. Clarkson, chief engineer; Thos. Kynman, assistant chief engineer; Thos. O. Cubett, senior shift engineer. Other members of the staff. some of whom are included in the above group are—Henry Jackson, Jr.; Frank Pitts; G. W. Holmes, senior shift engineers; Wm. Heath, general mechanic; A. Hostwell, assistant general mechanic; W. Whelan, head plumber; A. Ventres, and J. Williams, assistant plumbers; F. A. Russell, steam fitter; G. Ba'n, F. Murphy, and J. Cook, stoker operators; W. Harris, Jos. Scrodo, Dan. Simpson, coal trimmers; A. Matthews, cleaner and oiler; S. W. Cliff and Jas. B. Fisher, ice-making; P. Stapleton and H. H. Sloane, electric wiring; J. P. Doyle, H. O. Glennie, electric lamps and fuses; O. Leggie, G. Wilson. motors and elevators; J. P. O'Meare, office clerk, J. Wilkinson. storekeeper; Geo. White, general labor.

Just outside of the ice storage room is located three ice breaking machines which are used to reduce the ice blocks to the various sizes required for general use in the building.

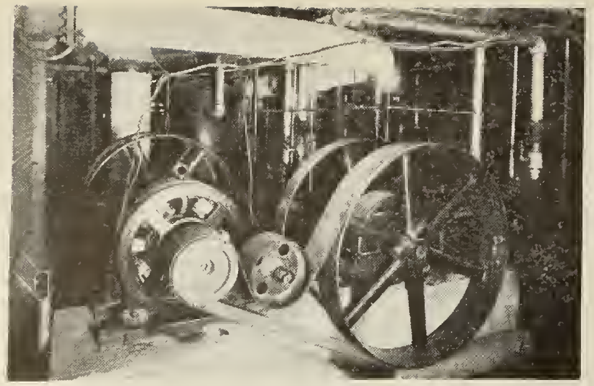
Besides the brine circulation for ice-making there are high and low temperature brine systems. The high temperature system is circulated by two circulating pumps, driven by two 10 h.p. Reliance motors, while the low temperature brine is circulated by two circulating pumps driven by two 5 h.p. Reliance motors. All the circulating pumps are Darling Bros. make. The brine circulation and compressed ammonia pipes used for direct expansion are all covered where exposed to atmosphere with cork insulation, manufactured by the Armstrong Cork and Insulation Company.

The electric motors used are controlled by square D switches made by the Cutter Hammer Co., Milwaukee, Wis.

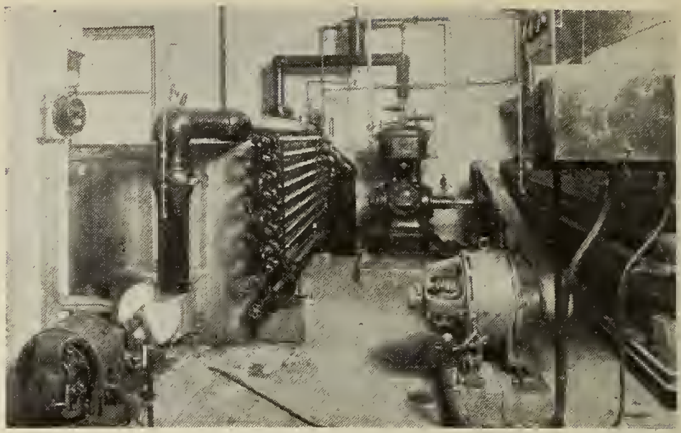
Automatic Refrigerating Unit

There is a complete automatic refrigerating unit located in the Pent House above the roof. It is intended to take care of the cold storage, refrigerators, etc., requirements of the banquet and convention halls. It consists of a Frick vertical enclosed type of compressor, 7½ tons capacity, belt-driven by a 10 h.p. Reliance motor, 220 volts, 800 r.p.m., also condenser coils and brine circulation to the refrigerators on the 9th and 10th floors. The brine is circulated by a circulating pump, made by Darling Bros., Montreal, driven by a 3 h.p. shunt wound Reliance motor, 11.4 amp. at 800 r.p.m. The automatic temperature control and all instruments used are made by the Foxboro Company, of Foxboro, Mass.

There has been provided an ammonia line from the main plant in the basement to the banquet hall for direct expansion and cold storage purposes, in addition to the refrigeration supplied from the Pent House.



Air Compressor Outfits.



Refrigerating Machine.

The principal sub contractors, for the power plant equipment and materials were as follows:

Armstrong Cork & Insulation Co.—(Cork) pipe covering.
Canadian Allis-Chalmers—Ornamental iron work.
Canadian Comstock.—Design and construction, electrical distribution.
Canadian General Electric Co.—Electric supplies and beaver duct.
Canada Cement Co.—50,000 bbls. of cement.
Canadian Fairbanks-Morse Co.—Platform scales.
Canadian Ingersoll Rand Co.—Air compressors.
Canadian Link Belt Co.—Coal and ash conveyors.
Canadian Westinghouse Co.—Generators, motors, transformers, etc.
Carmichael Waterproofing Co.—Roofing.
Crane, Limited—All steam and water pipes, also all valves used in low pressure steam work.
Cutler Hammer Co.—Circuit breakers on main switchboard.
Darling Bros., Ltd.—Circulating, vacuum pumps, etc.
Devoe Electric Switch Co.—Light and power panels.
Dominion Bridge Co.—Smoke stack and structural iron work.
Dominion Radiator Co.—Steam radiators.
Engineering Sales & Service Co.—Boiler erection.
Frick Ice Machinery Co.—Refrigeration equipment.
Giddings, A. A. & Co., Ltd.,—Transformers.
Johnston Regulator Co.—Temperature regulators.
Laurie & Lamb—Steam engines.
Mander & Lucas—Boiler settings and turner baffles.
Northern Electric Co.—Electrical supplies.
Otis Fensom Elevator Co.—Electric passenger and freight elevators.
Peacock Bros.—Steam pumps, meters, etc.
Robb Engineering Works—Water tube boilers, etc.
Sheldon's, Ltd., (Galt)—Keith fans, forced draft, etc.
Taylor-Forbes Co., Ltd.—Three ejector (sump) plants.
Taylor Stoker Co.—Underfeed stokers and engines.
The Cleaton Co.—Diamond soot cleaners.
The Garth Co.—Steam heating work.
Thos. J. Dyer Co.—Plumbing work.
Wm. Rutherford & Co.—Pipe covering (Philip Carey's).

EMERGENCY FUEL

As an emergency fuel, a mixture of fuel oil with fine coal in as large proportions as the coal will absorb and hold is suggested by the United States Bureau of Mines to steam coal users and gas manufacturers to augment their fuel supply during the present shortage.

Slack coal that has a high percentage through an 8-mesh screen, or which may be crushed to sizes of one-eighth inch or less, will take up in oil from 30 to 40 per cent. of its own weight and make a fuel high in calorific value. Coarse slack coal, however, as judged by a representative sample from the Pittsburgh market, will absorb oil to only 3 to 10 per cent. of its own weight, which would give a fuel having only about 4 to 15 per cent. increased heating value. The finer the size of the coal, therefore, the larger is the amount of oil which will be held. Tests made by the Bureau of Mines at its Pittsburgh experiment station indicate that the mixture can be made with either bituminous slack or anthracite culm.

This method bears a relationship to the Trent process of purifying coal by fine grinding and amalgamation with oil, now in operation at a plant at Alexandria, Va., which has demonstrated the success of a combination of oil and coal for steam-making, gas manufacturing and other fuel purposes. The present emergency proposal does not contemplate the cleaning process, but involves merely the simple mixing by shovel or concrete mixer. The Trent Corporation has volunteered to assist the Government in advising in the use or application of oil-coal mixtures, and to waive during this emergency any claim of infringement of its process which may or may not be involved by the simple mixing of fuel oil and coal, without reference to cleaning.

Chain grates and certain other automatic stokers are probably well adapted to handle the oil-fuel mixture if the bin and feeding devices are suitable. Oil-fuel mixtures will not fire spontaneously, but undoubtedly care should be exercised to ventilate bins where external heat may tend to drive off lighter gases, although the fuel oil which is on the market has had the lighter oils distilled from it.

This simple mixture of fuel oil and coal is proposed by the Bureau of Mines merely as a temporary measure. While under conditions of normal fuel supply such a mixture probably would not prove satisfactory unless it involved the cleaning feature embraced in the Trent process, in places where fuel oil is available it can be used to piece out a poor coal supply without the changes in equipment necessary to convert boilers to oil burning.

BRITISH PUMPS FOR SUDAN

A great deal of important irrigation work is in hand in the Sudan; and British firms are playing a prominent part in the manufacture and installation of the powerful pumps required for such purposes. Recently a British firm secured a contract for three 45 inch pumps driven by oil engines of nearly one thousand horsepower each. Each of these pumps is capable of delivering two cubic metres of water per second against a maximum head of close on 26 metres when running at 150 revolutions per minute; both engines are of the centrifugal twin series type. The contract included all the piping and auxiliary machinery, the latter consisting of two 50 horsepower oil engines for driving dynamos, motor driven circulating water pumps, charging pumps, and compressors.

Development of electrical power in South Africa is creating an active market for electrical equipment there.

In operating at about 75% of the present capacity, the U. S. steel industry is running at more than 100% of pre-war production.

Electricity in Its Infancy

By T. J. PACE

WE ARE only on the threshold of the Electrical Age. People who see the progress made in electrical applications, who now see trolley cars going where once the horse-drawn vehicle went; who are accustomed to having their houses lighted at the turn of a button; who have electric lights to make their streets as bright at night as in the day; who find their factories run by electricity; and who see the thousand and one ways in which electricity is saving time and labor—these people may think we are in a completely electrified world.

Nothing could be farther from the truth. As a matter of fact the work of the electrical industry has just begun. Business is good and is going to continue to be good for the next year. One of the reasons for this good business outlook is the vast amount of building, both of office buildings and homes. All this activity helps industry. The effects of this building increase are being felt in all kinds of industries, and particularly the electrical industry, for it will have its wiring and the installation of appliances, illumination, convenience outlets, etc., to do.

These new building projects are practically all to be electrified and perhaps this may seem to the laymen that we are living in a completely electrified world. But it is a fact that of all the homes in the country, only about 30 per cent. are wired for electricity and of the number which are wired, only about 20 per cent. are adequately wired. Right here is some business for the electrical fraternity.

This wiring proposition is not all of it, however. One of the biggest problems of the electrical industry is to supply homes with enough convenience outlets to take care of the increasing number of electrical appliances now being placed on the market.

Those who think that the world is completely electrified should know that the farmers throughout the country are now awakening to the advantages of electricity and that thousands of light and power units are now being installed where it is inconvenient for the central station to run power lines. The farmer is finding that electricity is a great saver of time and labor.

Of all the railroad mileage in the country, there is only about two per cent. electrified. This statement sounds as though there might be something the matter with railroad electrification. But the fact that there is not a large railroad in the country that is not now investigating the application of electricity to its lines only further bears out my first statement that electrical development is only in its infancy.

New Equipment in Chateau Frontenac; Large Tower Increases Cap.

Quebec.—Chateau Frontenac is destined to be one of the wonders of hotel construction when the new additions are completed, and this famous hostelry thrown open for the reception of guests in the spring of 1923. There is no need to describe the original chateau built on the promontory of Quebec, overlooking the St. Lawrence and with unrivalled scenic prospect. The object of referring to the Canadian Pacific hotel is not to describe the architecture, founded on the lines of a French chateau, but to speak of the steel concrete and fireproof tower and of the machinery and electrical fittings that are being installed on a scale of such magnitude as to be worth a featured description.

The enlargements and improvements to the Chateau Frontenac were undertaken in 1919, when the foundation of the twenty-story steel and concrete tower in the former hotel court yard was commenced. This tower, which has absorbed 2,800 tons of fabricated steel, has just been completed by the Dominion Bridge Co. and the roof is now being applied. The height of the tower is 500 feet above the level of the river and 300 feet above the solid rock foundation upon which it has been built. Besides the main offices, on the first floor, the tower will have three hundred additional bedrooms. The basement of the new chateau covers a large area. Here the boiler and engine rooms are located and the installation of the machinery practically completed.

There are three Goldie & McCulloch semi-marine water-tube boilers equipped with Jones underfeed stokers, Diamond soot blowers and all the latest instruments, such as Cambridge CO_2 recorders Craig damper regulators. Venturi feed water and steam flow meters are installed. Ashes are moved by steam jet. The boiler capacity is 325 and 260 horsepower, and with the type of stoker, 100 per cent. over-rating.

Engine Room Equipment

There are in the engine room two Belliss & Morcom (Birmingham, Eng.) engines, sizes 16 and 24 x 12, and 275 horsepower, Thomson motors and two motor generators. The large engine connects with a Westinghouse D. C. generator, 2,200 k.w., 220 volts, speed of 380 revolutions per minute. A small steam set engine, General Electric Co., connects with the D. C. generator, 150 k.w., 220 volts, and has 420 r.p.m. The large motor generator set is 200 k.w., 220 volts, which revolves at 900 revolutions per minute. A small motor generator set is 150 k.w. capacity, at 220 volts, 900 r.p.m. There is in addition one Crocker-Wheeler wheel balancer of 15½ k.w. capacity, and one Westinghouse balancer of 30 k.w capacity.

The Scotch switchboard embraces 15 panels. The first two are for strong synchronous motors, the next four generator panels, both motors and generators, D. C. The seventh and eighth sections are for two balance sets, the ninth panel for current heating, which will supply approximately 225 k.w., to supply kitchen ranges with heat at 110 volts. The tenth and eleventh section of panels connected with the switchboard are direct power feeders, supplying power for the six elevators, three passenger and three freight, and motors. The remaining four panels are for lighting and are capable of operating all machines in parallel, with a total capacity of 700 k.w. at 220 volts. For lighting, there is a three-wire system, 110 and 220 volts, and there are ammeter and power factor panels, double-throw aid switches and rheostats. The double current generator panels are equipped with circuit breakers of the reverse current type. The pole sight throws switches and rheostats and each panel has its own volt meter and ammeter. The balance of panels are equipped with three pole sight circuit breakers for starting the balancer sets, each equipped with double reaching volt meters and ammeters.

The A. C. heating panels are equipped with ammeter arc plugs so that the current in each phase may be determined. The two power distributing panels are equipped with signal throw switches. The lighting panels have pole signal-throw switches. The installation includes an electrical (Cambridge) CO_2 recorder, showing the percentage of carbon-dioxide in the flue gas. It gives readings each minute. There is a six-inch cushion of sand under the base of each machine to eliminate vibration, and the effect is wonderful, not the least vibration being felt, even in the engine room.

The entire machinery and electrical plant is being installed by the Canadian Pacific Railway building department, under the supervision of the company's chief mechanical and electrical engineer.

D. H. Mappes and his assistants are also to install 650 new radiators in the addition now in course of construction, besides miles of piping and electrical wiring, all insulated and enclosed in piping. The entire heating, lighting, etc., will be carried out in connection with the hotel machinery and electrical installation. Cold and hot air will be supplied throughout the building, as well as a system of ventilation from the engine room. The refrigerator service in all of the various storerooms, is fitted with the latest system in steel-concrete air block piping.

The roof will be of copper, and although the structure is every inch fireproof, a large steam pump will be installed which will pump water to every section of the building. The refrigerating installation comprises a ten compartment General Electric refrigerator with two

Practical Application of Mechanical Oscilloscope

Tuning Down High Speed Mechanisms so That Same Are Visible to Naked Eye—High Tension Current Employed for the Lamps—Use of the "Creeper" Gear

Minute visual examination of mechanisms operating at high speed is made practical by the use of a recently developed instrument known as the oscilloscope. A simple mechanical principle underlies the action of the Elverson oscilloscope, and its operation has been perfected after considerable experimenting on the part of the makers, Herbert Kennedy & Co., of London, Eng. Actually the oscilloscope is a commercial and workable application of the effect obtained when moving machinery is viewed in an intermittent artificial light. In such cases, however, the synchronism of moving parts with the frequency of the light flashes is purely accidental, whereas in the case of the instrument here described the results obtained are subject to delicate and accurate control.

Simple Method of Operation

Possibly the best estimate of the wide range of practical applications covered by this instrument will be obtained by first describing the method adopted for obtaining the desired result, and this is in reality remarkably simple. In the first place it must be remembered that the human organs of vision, including the eye, optical nerves, and the area of the brain concerned, require a definite time for operation, so that an impression, however transient, will, if sufficiently intense, occupy a definite period so far as the human capacity for vision is concerned. This period varies in normal cases between 1-10 and 1-5 of a second. In the second place it will be obvious that on account of the above considerations, all except slowly-moving parts of machinery will be invisible to the naked eye, or, at the best, visible only as a confused blur, on account of the multitude of different impressions which are received by the eye within a very short space of time.

If, however, the mechanism is rendered visible for a very minute period of time, after which comparative darkness supervenes, a definite image will be registered by the brain, whilst if several repetitions of this image occur within a fraction of a second, the effect will be correspondingly intensified as far as human vision is concerned. This briefly is the principle upon which the oscilloscope operates.

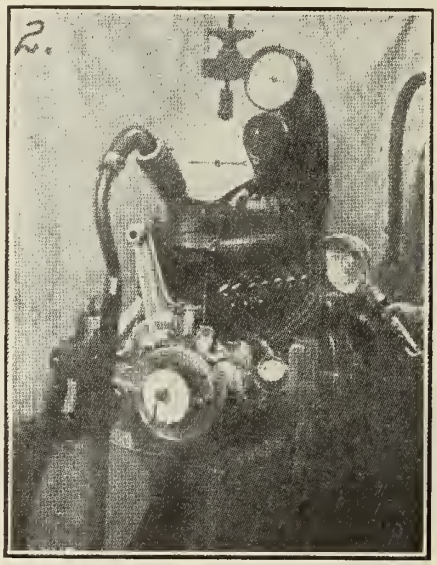

Fig. 2—Oscilloscope applied to automobile engine.

Essentially it consists of a special type of electric lamp which may be made to give a definite number of flashes of light per minute, the exact number depending upon the cyclic period of the mechanism which it is desired to examine. Thus the complete instrument comprises the lamp with an accumulator and induction coil and means for interrupting the current and controlling the number of flashes per minute. Considerable experiment was, however, necessary before these requirements could be embodied in practical form, and the equipment finally evolved is shown in Fig. 1.

This shows two lamps provided with shades and suitable holders and an accurately-made gear box, these units being connected up with an accumulator, induction coil, and condenser enclosed in a wooden case. It should be mentioned that the connections are so made that the equipment can be operated only when the lid is in position on the case, thus ensuring protection of the apparatus and of the operator against the high-tension current employed for the lamps.

Gas-Filled Lamps

The lamps are of a special gas-filled type, in which an electric discharge takes place between a point and plate electrode in an atmosphere of neon, these lamps having been evolved as the result of considerable experiment to give flashes of light of great brilliance and of exceedingly short duration. One of the lamps shown is a master unit upon which a control switch is fitted in the form of a spark gap which is rendered necessary by the intermittent nature of the current. This spark gap nullifies the effect of inductance in the lamp circuit, confining reactionary currents to the bulb, so that for a given current the maximum discharge is obtained between the electrodes. Consequently, since one or more lamps may be connected in parallel with the master unit, the maximum amount of light may be obtained from a given current.

Action of Gear Train

On the right in Fig. 1 is shown the gear box, which consists of a graduated circular casing in which two accurately-made gear trains are enclosed. Each of these trains receives its motion from a primary pinion on the central shaft, which is coupled directly to the mechanism to be tested, and each of them drives a contact breaker, which may be switched into the lamp circuit. In the case of one gear train, the speed is so arranged that the flashes of the lamp

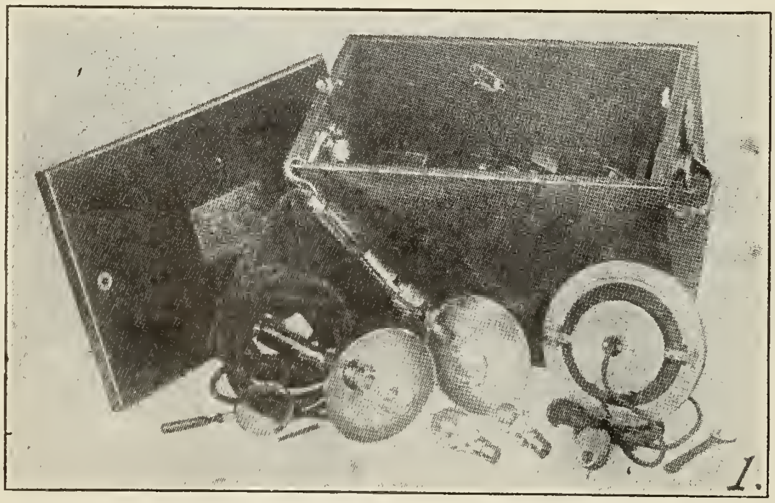

Fig. 11—Elverson oscilloscope and accessories.

synchronize exactly with the revolutions of the primary pinion, whilst in standard sets the other gear train gives 100 flashes of the lamp in 99 revolutions of the pinion. A switch working about the centre of the gear box brings either circuit into operation as desired, or, if required for special purposes, radial slides may be moved by hand to give one, two, or four flashes per revolution with either current.

In the case of the gear train where the number of flashes coincides with the number of revolutions of the primary pinion, it will be obvious that each flash occurs at a particular point in the revolution of the pinion. Thus the revolving member of the mechanism to be tested is illuminated in exactly the same position at successive revolutions, with the result that, if external light is sufficiently reduced, the mechanism appears to be stationary, although in reality it may be moving at a high speed. Similarly all parts mechanically coupled to the revolving shaft will be illuminated at definite points in the cycle of movements, so that any mechanism may be subjected to minute visual examination under actual working conditions irrespective of the speed employed.

Apparent Speed Reduction

On the other hand, if the alternative circuit or "creeper" gear is brought into action, successive flashes of the lamp will illuminate the mechanism in positions removed from one another by 1-100 of the cycle, despite the fact that actually the mechanism has passed through 101-100 of a complete cycle during the space of time between successive flashes. This, in effect, means that the apparent speed at which the mechanism is functioning is reduced to 1-100th of the actual speed, so that parts revolving at, say, 1,000 r.p.m. appear to be moving at the low speed of 10 r.p.m., at which speed, of course, visual examination is not only possible, but exceedingly useful, since the actual working movements of the parts are reproduced for inspection.

Typical Examination

If the primary shaft of the gear box be coupled directly to the cam-shaft of an internal-combustion engine, the action of the valve and rocker mechanism may be analysed minutely. Actual tests with the instrument have, in fact, already revealed a number of interesting points in connection with valve gear. Thus in many cases the lag which takes place in the closing of the valve when the valve stem is heated up may be distinctly observed, whilst failures of the roller to follow exactly the cam profile are equally noticeable. In the last-named case the roller may be seen to bounce on the cam and to be accompanied by a corresponding movement of the valve on the seating.

Testing Gear Action

Another important application of the device is in connection with gear testing, since errors in the interaction of two gears are rendered readily apparent. It should, of course, be pointed out that gears which apparently mesh correctly when running at 10 r.p.m. may exhibit several serious defects if the speed be increased to 1,000 r.p.m. or more. When using the oscilloscope, however, the majority of the defects remain apparent, whilst the speed at which the gears are revolving appears to be reduced, in this case by 100 to 1.

Actual tests show that periodic errors due to inaccuracies in circular pitch or lack of concentricity are visible as a slow oscillation of the various members of a gear train, whilst in cases where variable stresses are encountered in the drive the presence of backlash in the gears gives rise to the same visual phenomenon.

Studying Moving Mechanisms

Another important point is the fact that moving machinery may be made to appear stationary at any desired point in the cycle of operations. This is effected by moving the switch on the gear box to the stationary position, after which the complete unit, i.e., the gear box and contact breaker, may be rotated about its axis until the mechanism is observed to be in the desired position. This fact suggests several interesting possibilities in connection with the study of vibration and torsional stresses.

Thus in the case of machinery where an undesirable degree of vibration is apparent it will be found in the majority of cases that the vibration is periodic and synchronous with the movement of one of the main components. Whether this is the case or not may readily be determined by coupling the primary shaft of the gear box to the main revolving members in turn. If then the contact breaker is set so that two or four flashes per revolution are made, periodic vibration synchronising with the movement of the shaft will result in two or more images of the various parts being visible. Further, the planes or points where the amplitude of the vibration is at a maximum may readily be determined by setting the instrument to give two flashes per revolution and then rotating the gear box about its axis until the maximum distance is obtained between the two images. Thus it is possible actually to measure the extent of the vibration, and, in addition, to determine the direction and period of the movement, a factor which should be of great importance when testing high-class mechanisms with a view to improvements in design.

Examining Shaft Stresses

With regard to torsional vibration and torsional stresses in shafts, the method of application is equally simple, and in this case the protractor scale on the rim of the gear box housing is utilized. In the first place, the gear box is mounted in a suitable support, whilst two lines are scribed near opposite ends of the shaft to be tested, the lines being parallel to the axis of the shaft and in line one with the other. The primary shaft of the gear box is then coupled to the member under test, and both are rotated, whilst the contact breaker is switched to the stationary position so that the test lines become visible. The simplicity of this suggests developments in the direction of improved meth-

(Continued on page 40)

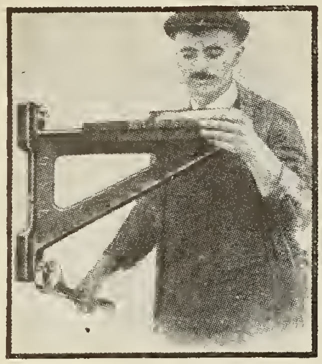
Some Factors in Power Transmission



Care Required When Installing Shafting—Figuring the Size of Shaft—Joints Should be Properly Made to Ensure Efficiency—Reducing Friction by Means of Ball Bearings

OPINIONS of engineers differ as to the best method of power transmission when a number of machines are to be operated in the one plant or department. Some advocate the individual, while others stick to the older method of grouping the machines and operating from one main shaft. Experience has shown that no fixed rule could be made as to the best method to adopt, and each individual case must be solved on its own merits, the solution being based on existing conditions.

Installing Line Shaft Supports

The fundamental consideration in the problem of power transmission is the erection of the line shafting that is to carry the numerous pulleys for driving the various machines. Where individual drives are used long lengths of overhead shafting are seldom necessary, but it is only in comparatively few plants that one will not see a line shaft of some description. It must be obvious that in order to obtain an installation of high efficiency great care must be given to the erection of the various brackets or hangers used for supporting the shaft. The practice followed when erecting a line shaft cannot be clearly defined, as the methods adopted by individual millwrights and mechanics will vary according to their own personal ideas and experience, as well as the local conditions governing each specific case. However, a brief outline may assist those who may have such a duty to perform. Each individual instance must be solved on its own merits, but the summary here given will be the practice recommended when erecting a line carried on ball bearings.

Placing the Hangers in Position

When the approximate location of the shaft has been determined, the hangers or brackets are arranged and secured in their respective positions and aligned by means of a spirit level and a taut string. During the process of securing the bracket or hanger to the wall or ceiling supports, a steel square is used to assure proper alignment of the machined surfaces that carry the boxes or ball bearing housings. It is advisable also to check the erection both horizontally and vertically by means of plumb lines. In the case of S.K.F. bearings the housings are thoroughly cleaned, the felt washers saturated with grease, and placed in the grooves in the housing. The lower sections of the housings are placed in their respective positions and the bearing seatings painted with cylinder oil to prevent the outer ring of the bearing from becoming firmly attached to the housing through the action of rust. Before placing the ball bearing on the shaft the latter should be wiped thoroughly to remove all grit and dirt.

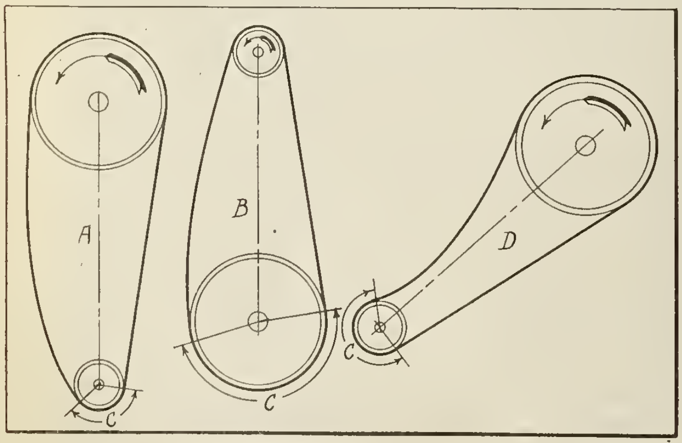


Fig. 1—Points to watch in vertical drives.

Placing and Aligning the Shaft

The shaft is then raised and placed in the lower sections of the plummer blocks, after which a spirit level is used to make final horizontal alignment of the shaft. The bearings are then fixed in their respective positions in the housings, by means of the locking nut. In the case of free bearings, care should be taken to make sure that the ball bearing fits into its seating in such a manner that the bearing as well as the shaft can move sideways with perfect freedom. When fixed in the desired position the sleeve nuts are firmly locked by the safety grub-screws. Before fitting on the upper sections of the plummer blocks the bearings are well lubricated. When bearings are supported in hangers, care should be taken to avoid excessive tightening of the top locking screw. Final alignment in a vertical plane is then made by means of a plumb line. Examination should not show the shaft rubbing at any point on the bearing housing.

Figuring the Size of the Shaft

When making calculations for size of shafting, it is well to use shafts of ample dimensions to take care of unexpected overloads and subsequent additions to plant equipment to be driven by that particular shaft. For the usual run of line shaft service, where supports are provided every eight feet or less, and where average loads and speeds are used, the shaft rating as given below may be considered good practice:

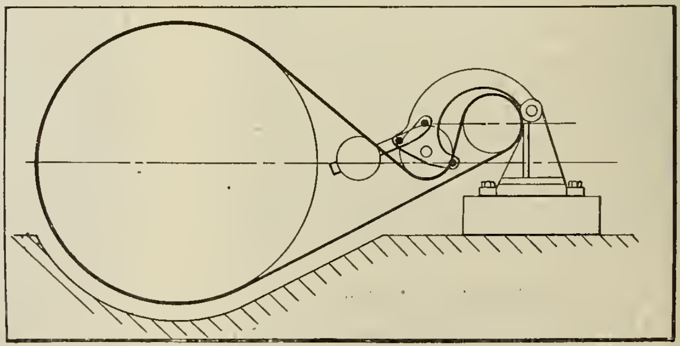

Fig. 2—General outline of Tenix short drive.

H. P. Transmitted by Steel Line Shafting

Dia. of Shaft	Number of Revolutions per Minute					
	100	150	200	250	300	350
1 1-16	6	8.9	11.9	14.9	17.9	20.9
1 15-16	8.9	13.3	17.7	22.2	26.6	31
2 3-16	12.6	19	25	31	38	44
2 7-16	17	26	34	43	52	60
2 11-16	23	34	46	58	69	81
2 15-16	30	45	60	75	90	105
3 3-16	38	57	76	95	114	133
3 7-16	47	71	95	119	143	167
3 11-16	58	88	117	146	176	205
3 15-16	71	107	142	178	213	249

A formula for above table would be:

$$H.\,P. = \frac{D^3 \times R}{83.7}$$

Shafts Subjected to Heavy Loads

When severe service is required, such as shafts carrying gear drives, large pulleys with wide belts, and where heavy loads and shocks are delivered at intervals or suddenly, a greater factor of safety should be taken. This is necessary to take care of the variations in the stresses on the shaft. A reasonably safe formula in such cases would be the following:

$$H.\,P. = \frac{D^3 \times R}{125}$$

where D = dia. of shaft in inches.
R = rev. per min.
H.P. = horsepower.

It will be understood that the table and formula given are only approximations. More accurate results may be obtained from the charts shown in Figs. 5 and 6. To use the chart it is necessary to calculate the twisting and bending moments of the shaft, based on the load, distance between supports and other factors. The figures between the heavy black lines indicate the h. p. at the point of intersection of the bending and torsional moments. The charts are based on the formula:

$$D = \frac{\sqrt[3]{5.1 \times (M + \sqrt{M^2 + T^2})}}{S}$$

when:
d = Shaft diameter in inches.
M = Bending moment in inch-pounds.
T = Twisting moment in inch-pounds.
S = Fibre stress in pounds per sq. in.

Stress and Tension in Belts

When a belt is stretched over a pair of pulleys, is cut to the proper length and laced together to form an endless band, it is obvious that uniform tension will exist throughout all portions of the belt, as long as the same is at rest, due to the tightening exerted by the lacing. If the distance between the respective shafts is considerable, the weight of the belt itself will increase the tension in that section of the belt near the pulleys. This increase of tension due to the weight of the belt would make but little difference in the unit-stress of the material, so it is safe to assume that the tension is equal at all points when not exerting a pull.

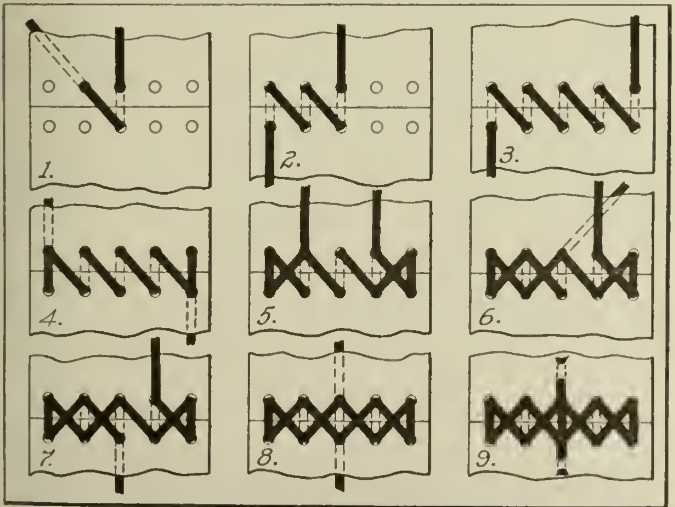

Fig. 3—Showing sequence of lacing belt.

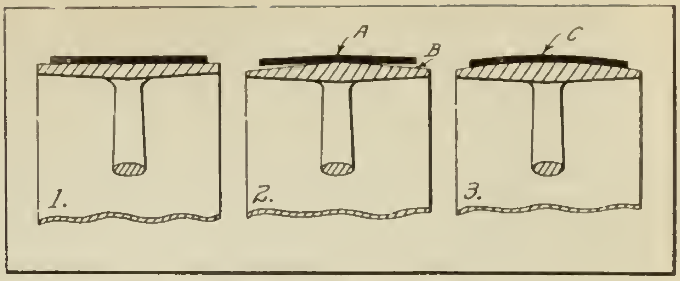

Fig. 4—Flat and crowned pulleys.

In the process of transmitting power, however, the condition of stress in the belt is materially changed. Owing to the flexibility of the belt it is only by pulling that power can be transmitted to the other shaft, so that increased tension is evident in the power side of the belt, the opposite side developing a sag or slackness caused by the stretch due to load resistance. The sum total of the tight and slack side tensions is approximately the same as the uniform stress when belt is at rest. The amount of pull that can be applied to a belt is limited by the tension at which the belt slips around the pulley. Since the force of friction between belt and pulley is dependent upon the normal force with which the belt is pressed against the pulley, and the coefficient of friction between the two, it is obvious that the tighter the belt is laced, and the rougher the contact surfaces, the greater is the power that can be delivered by the belt. From this it would appear that it is possible to transmit any amount of power through any size belt, if such belt were only laced tight enough.

While theory might lead us to this conclusion, the same would be impossible in practice, as no belt would stand the strain. Other practical conditions are likewise involved which fix the limit of power transmitted at a point far below the breaking strength of the material.

Effect of Centrifugal Action

When the belt, as it passes around the pulley, changes its straight-line direction to circular motion, each particle of the belt — like a body whirling at the end of a cord about a centre of rotation — tends by centrifugal force to fly away from the surface of the pulley, thereby decreasing the normal pressure, and hence the friction. This centrifugal action also changes the tension in the belt between the pulleys. As the centrifugal force increases in proportion to the square of the linear velocity, it is evident that the effect is greater at high speeds than at moderate or low speeds.

A further circumstance that affects the driving power of a belt is the stiffness of the leather or other material of which the belt is made. When passing around a pulley, the belt is bent to conform to the circumference, and is again straightened out as it leaves the pulley. It is evident then that the theoretically perfect action is modified somewhat according to the nature of the bending and the thickness or flexibility of the belt, so that a small pulley carrying a thick belt would be the worst case for successful theoretical calculations.

Joints Should be Properly Made

A very important factor in power transmission by belt is that of the laced joints. This, naturally, is the weakest portion of a belt and therefore special care should be exercised in seeing that the connection is properly made. The first thing to consider is the cutting of the belt ends. This must be carefully done. The ends should be cut perfectly square with the run of the belt and the holes in each end properly aligned with each other. An effective method of lacing is shown in Fig. 3. In all cases it is advisable to have the laces on the pulley side of belt running parallel, the crossing being made on the back. Knots should not be used. The best practice is to lock the lace by passing it through an extra hole and pulling it tight. A cut is then made in the lace just

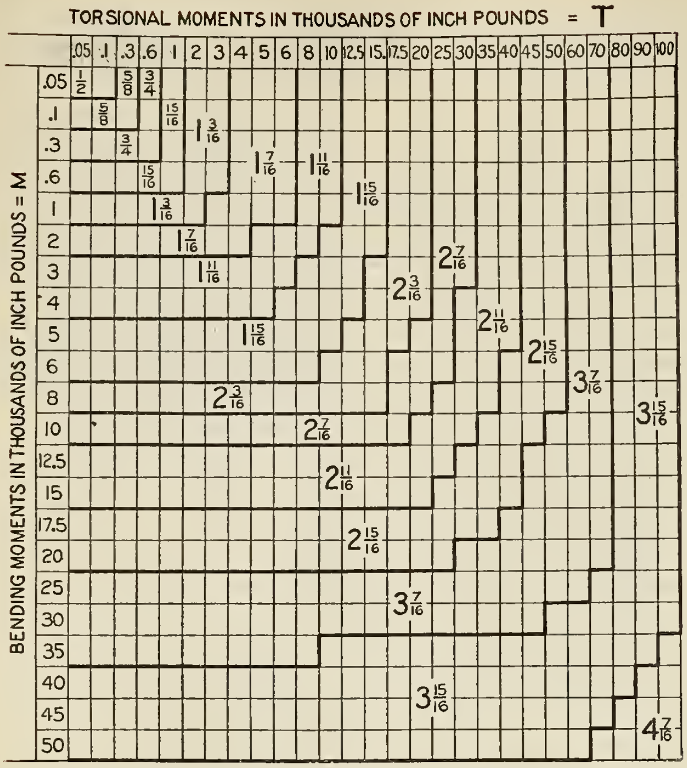

Fig. 5—Chart for finding the h. p. of shafts of small diameter.

clear of the hole, and about half way through, at an angle to prevent lacing pulling back. The lace is then cut off about ¼ in. back of lock.

Crowning the Pulley Face

The crowning of pulleys is a very important feature. A flat faced pulley would give the highest frictional value, but unless conditions are ideal, it is difficult to keep the belt on the pulley. It is general practice to crown pulleys on which the belts are permanently running. There are two methods in use, the flat conical crown and the spherical crown. In the former the apex of the crown is a pronounced point as shown in Fig. 4, and the tendency is to make a poor contact with face of pulley. The method shown at Fig. 3, where the face is rounding, is the better way as it permits a more uniform bending of belt fibres.

Different Systems of Rope Drive

Properly designed rope drives are highly economical and efficient in many situations, for transmitting power between long centres, at angles, around obstructions and particularly where larger units of power are to be carried. The flexibility of manila rope, its positive operation, relatively low cost and long life give it many advantages.

There are two systems of rope transmission. What is known as the English system is made up of individual ropes, separately spliced and running constantly in the same groove of the driving sheave and of the driven sheave. Due to more or less unequal stretch, it is almost impossible even to approximate uniform tension on all the ropes. Consequently it is usual to employ ropes of larger diameter and load them heavily. English system drives are practicable only when the ropes run horizontally or nearly so and in some such situations they are very satisfactory.

The fundamental principle of the so called American system of manila rope transmission is that one continuous rope is used (with only one splice), which travels consecutively through all the grooves of the sheaves and which runs continuously around a winder and tension carriage arrangement, that keeps the rope adjusted at a uniform tension throughout its entire length at all times, for ordinary variations in load. The American system is far better adapted and more efficient for most service.

Efficiency of Rope Drive

The successful operation of any rope drive is dependent primarily upon the design and the proper adaption of those principles which have been demonstrated by experience to govern efficient rope drive practice. The diameters of the sheaves in relation to the diameter of the rope and the speed are important. The location of the tension outfit and how the rope leads to and from it also are vital factors.

The diameter of rope to select, the number of wraps, the form of the sheave grooves, the general arrangement and location of the sheaves, the "wind" of the rope and other questions are individual problems with each drive. They can be answered only from an extensive experience with rope drives for all kinds of service.

To plan a rope drive, complete and definite information is required about the conditions of service. This data should be accompanied by a rough sketch showing the layout of buildings and equipment. The information required to enable engineers to prepare plans and estimates for rope drives is specified below:

The approximate amount of horsepower to be transmitted.

The type of unit that supplies power to the driving shaft and the class of equipment that power is to be delivered to.

Direction of rotation and speed of the driving shaft; also that of the driven shaft.

The diameters of both shafts.

The location of both shafts and their position in relation to adjacent floors, ceilings, walls, posts and other obstructions. This is necessary to properly determine the sizes of sheaves and the location of tension equipment.

How close bearings can be placed on each side of both driving and driven sheaves.

The centre distance of the shafts and whether they are parallel and on what level.

It should also be stated whether the ropes have to clear any obstruction.

Considering the Friction Loss

Present-day factory operation demands that every possible source of leakage be eliminated, or at least minimized. A frequent, and very often inestimable, cause of leakage is the power loss caused by inefficient or faulty transmission installations. Owing to the variable stresses that hangers, shafting and bearings are constantly subjected to, it is imperative that great care be exercised when erecting all classes of shafting that is to transmit power. Friction in bearings is one of the chief sources of lost power. With modern ring-oiled bearings the frictional loss may be reduced considerably, but even with this type of bearing the best results are only obtained after the bearing has been well "worn in," and in attaining this objective, constant care and attention is requir-

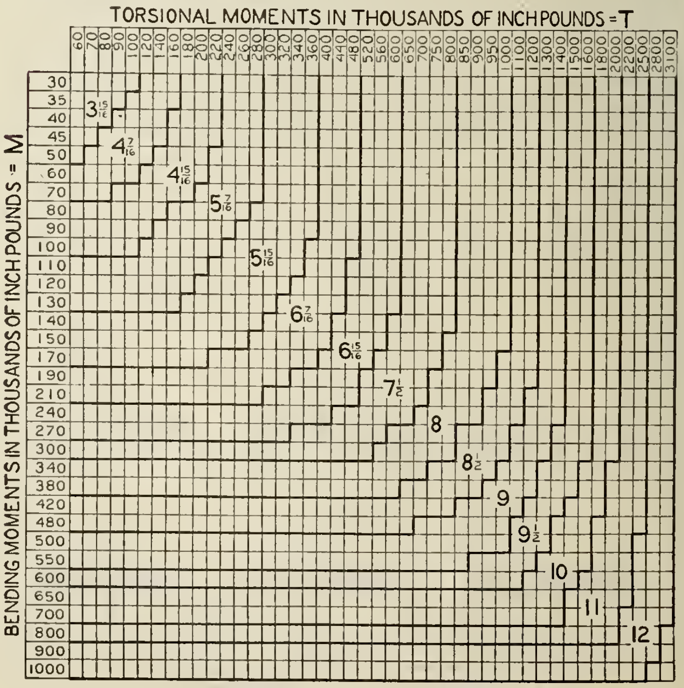

Fig. 6—Chart for finding the h. p. of shafts of large diameter.

ed to see that the oil supply is adequate and shafting kept in perfect alignment.

Allowance for Shaft Deflection

By equipping line and counter-shafts with ball bearings, the cost of lubrication and attention is reduced to a minimum; there is no necessity for "wearing in," and the starting effort is almost negligible. It is essential, however, to avoid bearings of a rigid construction, and provision should be made to counteract shaft deflection, a condition that is invariably present in some form or other when long lengths of shafting are subjected to a number of varying and opposing stresses. Some bearings are designed with swivel housings, but considerable unnecessary strain is often placed on the balls when the bearing is under heavy load. In self-aligning bearings any deflection of the shaft is taken care of by the special arrangement of the housing that permits the balls to roll sideways in the spherical ball race. This instantaneous response to shaft deflection minimizes loss through friction.

The problem of friction loss in transmission equipment must be faced by the engineer sooner or later. It is generally conceded that well designed ball bearings have a lower co-efficient of friction than the plain bronze or babbitted bearing. Few of the plain bearings will register an efficiency greater than 80 per cent. and when poorly installed may show a loss through friction of 30 per cent. or even greater. By the installation of ball bearings this loss has been reduced by upwards of 70 per cent.

Typical Example of Power Saved

As a typical example of the saving possible through the use of ball bearings we will assume that 40 ft. of 3 in. shafting is carried on five plain bearings, the power delivered being 60 h.p. at 250 r.p.m., the total load on the five bearings, including pulleys, belt pull, etc., being about 18,000 lbs. Placing the co-efficient of friction for a plain journal bearing at 0.04, the friction load will be:

$$18{,}000 \times .04 = 720 \text{ lbs.}$$

This gives the ft. lbs. per minute, as:

$$\frac{720 \times 3.1416 \times 3 \times 250}{12}$$

and the h. p. absorbed by friction in the plain bearing of:

$$\frac{720 \times 3.1416 \times 3 \times 250}{12 \times 33{,}000} = 4.28 \text{ h. p.}$$

For well designed ball bearings the co-efficient of friction will seldom exceed .002, so that the loss in such cases would figure out at:

$$\frac{36 \times 3.1416 \times 3 \times 250}{12 \times 33{,}000} = .214 \text{ h. p.}$$

This indicates an approximate saving in power of:

$$4.28 - .214 = 4.06 \text{ h. p.}$$

Aside from the actual power saved, a feature of economic advantage is the low starting effort required for shafts equipped with ball bearings, as the initial pull is relatively the same as when running.

In making calculations for and the selection of suitable bearings, it should be borne in mind that tables generally give the sizes for steady loads and speeds, so that where bearings are subjected to shocks, ample margin should be allowed in excess of the load stated. For this reason it is recommended that a reasonable factor of safety be used when figuring.

Rules to Follow When Installing

When fitting a line shaft with ball bearings it is advisable to adhere to certain conditions. These might be stated briefly as follows: One bearing only should be fixed axially on each independent line of shafting; it is advisable to locate this fixed bearing as near the centre of shaft length as possible; bearings on either side of fixed unit must be located centrally in the housing and be free to move laterally in either direction; where sleeve nuts are used for tightening or adjusting, they should be screwed on in the direction opposite to shaft rotation; be sure and tighten grub screw that locks the sleeve nut; see that ball race is well lubricated with the necessary grease.

The Lenix Short Drive

Lack of sufficient space frequently restricts the length of drive that can be used. In such instances it is generally the practice to fit up an idler to make up for the loss of centre distance. This is especially true when there is a great difference between the diameter of driver and driven pulleys. Fig. 2 illustrates the application of the Lenix flexible idler as used on equipment such as ice machines, air compressors, etc., where the shaft centres are necessarily close together. It is important, however, in obtaining effective service from a drive of this character that a belt be selected with a high degree of pliability and one that will not break down readily under the constant changing positions of belt fibre.

Tension and Power Transmitted

When a belt is working at its full efficiency the pull on the tight side will range from 60 lbs. to 120 lbs. per inch of width for single belts, this stress varying according to the thickness of the leather from which the belt is made. A fair working average is about 90 lbs. per inch of width. For double belts this is increased to approximately 150 lbs., the average between the range of 135 lbs. for light and 160 lbs. for heavy leather. In order that the belt shall do its maximum work the strain in lbs. on the slack side of the belt must bear a certain ratio to the pull tension that slippage does not take place. In practice this ratio will be about 1 to 3, dependent on the condition of the belt and pulley surfaces, and on the percentage of belt contact. Safe practice places the ratio at 1 to 2, so that a fair average for stress would be 45 lbs. for single and 75 lbs. for double belts.

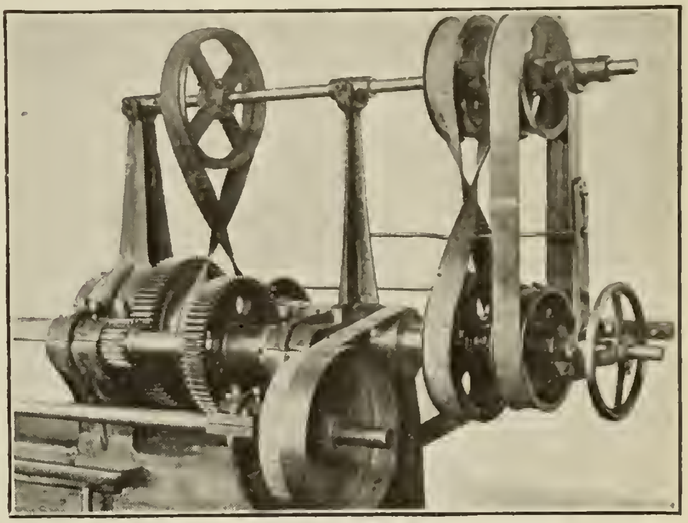

Fig. 7—Interesting arrangement of belt drive.

The following rule will be suitable for determining the power capacity of any given belt: multiply the belt width in inches by 45 for single and 75 by double belts, and by the speed in feet per minute, dividing the product by 33,000. The result will give the h. p. delivered by the belt. Suppose a 4 in. single belt is running at 1,200 ft. per min., the result will be found by the rule given, using it in the form of a formula:

$$H = \frac{w \times t \times v}{33{,}000} \text{ where}$$

H=horsepower; w=belt width; t=tension; v=velocity.

$$H = \frac{4 \times 45 \times 1{,}200}{33{,}000} = 6\tfrac{1}{2} \text{ h.p.}$$

For a 10 in. double belt running at 1,500 ft. uer min., the h. p. transmitted would be:

$$\frac{10 \times 75 \times 1{,}500}{33{,}000} = 34 \text{ h.p.}$$

It is always advisable to use pulleys as large as possible, as the action of the belt in passing over small pulleys creates stresses in the belt that add greatly in shortening its life. The percentage of the pulley circumference in contact with the belt has a vital effect on the friction between the two elements. It is obvious if the belt contact exceeds 180 deg. the friction will be greater than when less than half the circumference is covered. At the same time it will be understood that what is gained on one pulley of a connected pair is lost on the other. However, when the slack side is on top any sag in the belt when operating under load will add to the power factor. If an idler is used it is best located near the smaller pulley and on the sagging side of belt. A glance at Fig. 1 will show the advantages of proper installation of vertical or oblique drives. The ideal belt drive is the horizontal, but this condition is not always possible so that some alternative must be resorted to. In Fig. 1 the drive shown at A would be very inefficient as the contact on the small pulley is reduced as the speed increases. That shown at B is better as the effect is not so pronounced when the large pulley is the driven and at the bottom. Vertical drives should not be encouraged and some modification between it and the horizontal will give better satisfaction. A serviceable drive is shown at D, where the sag of the belt due to load causes the belt to increase its wrap around the small pulley and thus add to power transmitted. The efficiency of a belt when running horizontally will be reduced about 30 per cent. when operated at an angle of 70 degrees.

ELECTRICITY IN ITS INFANCY

(Continued from page 33)

The same thing is true of the inland waterways and ocean steamship companies. Nearly all of them, to-day, are working on the application of electrical propulsion to their own particular problems.

It is true, also, of the industries. The steel, coal, mining, in fact, all the fundamental industries of the country, are working on their own electrification problems.

The world, to-day, is not electrified. It is just becoming electrified. Within the next few years there will be a thousand-fold increase in electrification, which means, of course, that the life of every citizen in Canada is going to be affected indirectly, perhaps, but directly for the most part. Electricity and the electrical industry is just in its infancy.

The total cost of the bridge to be constructed at Ile Perrot, Que., for the Dominion and provincial governments will be approximately $260,000. Work on the superstructure will be carried out by the Dominion Bridge Co. at a cost of about $125,000, the remainder of the work being awarded to the Dufresne Construction Co.

Reasons Why Belts Slip on Pulleys

IN NEARLY every plant there are some drives in use on which more or less trouble is experienced because of the belts slipping on the pulleys, and it has become quite a common practice to endeavor to overcome this by lagging the pulleys with some special covering or by use of applications which tend to hold the belts and pulleys together when they are in contact.

The results obtained by the use of these expedients can be satisfactory only to a degree for while in many cases they apparently correct the difficulty it is quite probable that a really careful investigation will bring out that the trouble which manifested itself in belt slippage has been transformed into another form which is not so evident as was the slippage and consequently is overlooked altogether. Increase in friction in bearings is one common form which this transformation takes, and the result is a decrease in the efficiency of the power unit, which not only backs up directly to the coal pile and the money box, but is a steady boarder.

It is much like trying to cure a surface manifestation of an infection by putting on a salve. You may drive it away from some particular spot, but it will show up somewhere else and will continue to do so until you remove the cause of the infection.

There are two factors which fundamentally influence slippage—one is the resistance to slip exerted between the two surfaces which are in contact, and commonly referred to as the co-efficient of friction, and the other is the pull in the belt which is the cause of the tendency to slip. Therefore, when a belt slips on a pulley, assuming that the belt is pliable and conforms readily to the face of the pulley, it may be either because the co-efficient of friction between the belt and the pulley is too low, or because the belt pull is too great.

In probably nine hundred and ninety-nine cases out of a thousand, it is because the belt pull is too great, and manifestly the logical and rational thing to do is to decrease the belt pull, not only because it constitutes the removal of the cause of the trouble, but because it decreases the wear on the belt and decreases the friction in the bearings, and as a consequence reduces the demand on the coal pile and the drain on the money box, while increasing the co-efficient of friction accomplishes none of these advantages.

The amount of power a belt transmits is calculated by multiplying the belt pull by the belt speed, so it will be seen that if the belt speed is increased the belt pull can be decreased, and the same power will result. For instance: If the belt pull is 800 lbs. and the speed 3,000 ft. per minute, the same amount of power is being transmitted as if the pull were 600 lbs. and the speed 4,000 ft. per minute, and when you stop to figure that in the transmission of power there is a tension in the belt on both the pulling and slack side when the drive is standing still, which throws a side pull on the bearings of pretty close to twice the working pull, it will be seen that cutting down the belt pull means a great deal.

In this particular illustration the total reduction in the side pull on the bearings is something like 600 lbs., while the pull tending to cause slip on the pulleys is cut down by 200 lbs., and it is all accomplished by increasing the diameters of the pulleys. The real cure for belt slippage and at the same time a profitable dividend paying investment is:

1st. See that the belts are pliable so that they conform to the faces of the pulleys, and then

2nd. Increase the pulley diameters so that efficient belt speeds are obtained, and the belt strains are brought down to within reasonable limits.

PRACTICAL APPLICATION

(Continued from page 35)

od of measuring horsepower under actual running conditions, since with a shaft of given dimensions and material the angular displacement of torsional strain bears a constant relationship to the load applied.

As indicating the practical applications of the oscilloscope, the accompanying illustrations may be of interest. Thus in Fig. 2 the equipment is shown attached to the half-time shaft of one of the latest types of engines, the object in this case being to examine the working of the valve gear. To attach the primary shaft of the gear box to the desired part, a simple form of adapter is supplied. Some difficulty may, of course, be experienced in the examination of parts which must necessarily remain enclosed, but in this connection it may be mentioned that a considerable amount may be seen through a very small aperture, since the light may be projected in any desired direction, whilst the images formed are perfectly clear and definite.

The last-named point will be appreciated on referring to Figs. 3 and 4, which are reproductions from actual photographs of the headstock of a sewing machine running at approximately 1,500 r. p. m. In the case of Fig. 3 it will be seen that the moving parts present the usual blurred appearance which precludes the possibility of visual examination of the majority of the components. In Fig. 4, however, every part is distinctly visible, although during the time of the exposure necessary to secure the original photograph the machine made upwards of 2,000 revolutions.

Incidentally it may be mentioned as a curious fact that in general the clearest images are obtained when the mechanism is running at the highest speed.

Canadian Coal Output Affected by Strikes

Eleven Disputes Between Employers and Employees—Production Slightly Less Than Last Year—Four Million Tons in Interprovincial Trade—Large Quantities Imported From England

By S. J. COOK
Chief of Mining, Metallurgical and Chemical Branch, Dominion Bureau of Statistics

OUTPUT of coal from Canadian mines during the twelve months of the calendar year 1922 was approximately 14,210,000 tons as compared with 15,057,493 tons in 1921; 16,946,764 tons in 1920; and 13,919,096 tons in 1919. The great strike which tied up the United States coal mines for several months was reflected in Canada and resulted in a loss of 1,199,427 working days. Eleven disputes between employees and employers occurred in the coal mining industry in Canada during the eleven months ending November, nine of which were in Alberta and South-eastern British Columbia, and the other two in Nova Scotia. In all 23,901 men were affected, and of the time lost, 931,960 days were lost in the strike which began on April 1st, and 260,034 days' time was lost in the short strikes originating in August. Having in mind the fact that over one million working days' time was lost by the employees of the coal-mining industry during the year the output of fourteen and one-quarter million tons may be considered quite satisfactory. Alberta coal mine output amounted to 5,387,000 tons, a little more than half of which was lignite and nearly all the balance bituminous. Nova Scotia contributed 5,349,000 tons and occupied second place among the coal-producing provinces. British Columbia accounted for 2,936,000 tons, and New Brunswick and Saskatchewan followed with 289,000 tons and 250,000 tons respectively.

Interprovincial Coal Shipments

Four million tons of Canadian coal moved in interprovincial trade during the year, and of this amount about 2,443,000 tons was bituminous coal, the balance being mostly lignite. Shipments of Nova Scotia coal to other Canadian provinces, principally New Brunswick, Prince Edward Island and Quebec, amounted to 1,982,000 tons. The Province of Quebec received about 1,600,000 tons of Canadian coal during the year, an increase of nearly 700,000 tons above the receipts of Canadian coal in the preceding year and fully six times as much as reached this province in 1920.

The restoration of the St. Lawrence trade to the normal pre-war figure of 2,000,000 tons per season was therefore almost overtaken during the twelve months just closed. Shipments of Canadian coal into the province of New Brunswick totalled 360,000 tons, while the shipments from that province to other points in Canada amounted to 63,000 tons. Only about 10,000 tons of Canadian coal was shipped into Central Ontario during the year. Manitoba and the section of Ontario lying west of Fort William and Port Arthur received approximately 600,000 tons. Saskatchewan's receipts of Canadian coal were about 1,267,000 tons, while the shipments from that province for domestic trade were slightly under 100,000 tons. Alberta coal to the extent of 1,829,000 tons found its way to other Canadian provinces and 85,000 tons of British Columbia coal was also shipped for consumption in other parts of Canada.

Coal Imports and Exports

Exported Canadian coal amounted to 1,821,000 tons for the year comprising about 1,000,000 tons from the western provinces and the balance from the Maritime Provinces. In spite of the strike the amount of Canadian coal exported during the twelve months ending December, 1922, was only about 160,000 tons less than in the preceding year. The exports during 1920 were 2,558,000 tons, and in 1919 amounted to about 2,000,000 tons.

For the first time in many years quantities of coal were imported from Great Britain and in all about 874,000 tons was received, 710,000 tons of which was bituminous and 164,000 tons of which was entered as anthracite. The receipts at customs ports in Quebec of this coal from Great Britain amounted to 812,000 tons during the year, while New Brunswick received 47,000 tons and the balance was equally divided between Ontario and Nova Scotia. Imports of coal from the United States amounted in all to 13,937,000 tons, comprising 11,254,000 tons of bituminous coal and 2,683,000 tons of anthracite coal. As compared with the records for the preceding year the imports of bituminous coal were 2,300,000 tons lower, and the imports of anthracite were 1,885,000 tons less. Comparison with 1920 figures would indicate an even greater shortage as the imports of United States bituminous coal in that year were close to 16,000,000 tons and the anthracite imports came very near 5,000,000 tons.

Statistics have been prepared showing for each of the past three years the output, interprovincial movements, exports for foreign trade and imports for domestic consumption of anthracite, bituminous and lignite coal for each province in Canada and from the data given there has been deducted the amount of coal made available for consumption in each provincial division. For the whole of Canada the apparent consumption, or more properly, the coal made available for consumption in 1922 amounted to 27,200,000 tons and included 21,228,000 tons of bituminous coal; 3,083,000 tons of lignite; and 2,888,000 tons of anthracite coal. The principal coal-consuming province, as indicated in the table, was Central Ontario in which 9,849,000 tons was made available, including 1,716,000 tons of anthracite coal. In 1921 the same area was supplied with 11,543,000 tons and in 1920 with 13,331,000 tons. For Quebec the data given show that 4,450,000 tons of coal was made available in 1922 as compared with 4,898,000 tons in 1921, and 5,327,000 tons in 1920.

Coal mined in one province is sometimes shown as exported from another province, a notable instance being that the bulk of coal exported from the Province of Alberta is shipped through the customs ports of Fernie and Cranbrook, in British Columbia, while some Nova Scotia coal is exported through the port of St. John, New Brunswick.

Statistics show that in 1920 Canada produced 16.9 millions tons, exported 2.5 million tons, imported 20.8 million tons, and thus apparently consumed 35.2 million tons. In 1921 when the output was 15 million tons, the quantity exported amounted to 1.9 million tons, imports to 18.1 million tons, and the apparent consumption was 31.1 million tons. The decline in the consumption of coal in 1921 was in conformity with the prevalent depression in the industrial world. For 1922 the output was 14.2 million tons, the exports 1.8 million tons, the imports 13.9 million tons from the United States and 0.8 million tons from Great Britain, so that the apparent consumption was 27.2 million tons. The decrease in every item was due to the strikes prevailing during the year, although the apparent consumption of 27.2 million tons was also partly due to depressed industrial conditions. The output towards the close of the year was decidedly improved.

Motor vehicles registered in Canada during the year 1922 numbered 470,000, as compared with 402,029 cars in 1920 and 2,100 cars in 1907, according to the latest government figures. During the past four years the car registration in Canada has almost doubled, and the Dominion now holds second place in per capita possession of automobiles—about one car to every eighteen people.

Mount Royal Hotel

HOW VERY soon we adapt ourselves! The travelling man who for weeks and months has been travelling through the more sparsely populated districts of our country, accepting the poor conveniences and homely accommodation of smaller hotels, which in many cases are mean in the extreme, has the good fortune to eventually blow into one of our larger towns. He casually walks into one of the largest hotels and with little or no thought, quickly accommodates himself to the modern conveniences and luxury that are afforded him without even considering the cause of this wonderful transformation. If he should happen to be of an inquisitive turn of mind, he will slowly retrace in his mind the source from which these benefits are derived. In so doing, he will ultimately find himself in a labyrinth of pumps, boilers, engines, dynamos, refrigerating apparatus, etc., in the basement, and last but not least, confronted by a competent staff of engineers whose duty it is to see that every portion of this apparatus is functioning correctly. It is this apparatus that we have briefly described in this issue, but which gives but only a slight conception of the enormous equipment that a hotel of this proportion requires. Needless to say, it would be a presumption to attempt to describe many of the interesting features of the mechanism in the space we have taken, but we can leave that for some future date when we can treat with each machine or apparatus separately and in a more complete and exhaustive manner.

Our large hotel companies are realizing the necessity of keeping abreast with the times. In their endeavour they are utilizing all the ingenuity that brains and science can produce to promote greater comfort for their guests and are sparing no expense in their effort. We can therefore see that we have a condition that is conducive to growth from which has crystalized a monument of architectural and engineering perfection and embodied in the new Mount Royal Hotel of Montreal.

Canada's National Resources

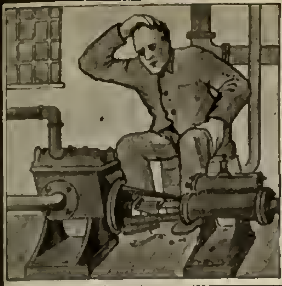
WHILST we are looking around and bemoaning the fact that there is comparatively little or no hard coal coming over the border from the States, our minds naturally turn to the resources of Canada and wonder to what extent we are self supporting. It is most refreshing whilst we are in this state of mind to hear it announced that Canada has an extensive natural product in the form of Helium gas, which is peculiar to one district in Alberta alone, where the natural gas contains 36 per cent. We are also informed that Professor J. C. McLellan, of Toronto University, can now produce this gas in commercial quantities at a very cheap rate.

The history of this gas is one of the romances of science. It was recognized and its spectrum identified more than 50 years ago, but it was not until 1895 that Sir William Ramsay, discovered and actually isolated a portion of it. The cost of producing even a very small amount of gas at this time was so high that the gas could not be utilized for any commercial purpose. It was, however, during the war that Prof. McLellan was sought out by the British Admiralty and appointed scientific adviser, in which capacity he performed a very valuable war service.

He was successful in generating this gas sufficiently cheap to bring it into the domain of ordinary usefulness, when it was used instead of hydrogen for inflating war balloons. Its value was of the highest importance on account of it being non-inflammable, whereas hydrogen was known to be dangerous from many standpoints. And now after two years' industrious research helium gas has been liquefied at 484° F to below the freezing point of water, and through which process the gas can now be produced at an extremely cheap rate.

From a scientific standpoint it now makes it possible to undertake research of a varied character in the interests of physics, refrigeration and chemistry, and before long it may possibly be introduced as a commercial proposition on account of the peculiar properties of the gas at this low temperature. Some of the peculiar properties of the gas in its liquified state, are that materials brought in contact with it, modify their physical peculiarities and characteristics in a most pronounced manner. For instance lead and rubber, which at ordinary temperatures are most pliable, can be made to become most brittle, and the magnetic properties of many of the elements become intensified. At this early stage it is hardly possible to suggest for what purpose this gas may be ultimately used, and what further avenues of science may be opened for research due to its discovery.

It may not be generally known, but during the war Prof. McLellan distinguished himself most brilliantly with the Admiralty Dept. It was during the gloomiest days of the German submarine campaign, he succeeded in perfecting the hydrophone, which very materially helped to combat this awful menace. And now in further view of his recent discovery, we feel proud that Canada can produce such a scientist, and in view of him refusing exceptional offers from abroad, he has proved himself to be a Canadian through and through, and a Canadian for Canada.



OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

Question:—Would you kindly inform me through your paper the working pressure we could allow on our hydraulic press the accumulator being 4 in. bore and 2¾ in. thick; the cylinder 14 in. inside diameter, and 4 in. thick and the piping ½ in. bore and ⅜ in. thick—all cast iron?

H. H. Orillia.

Answer:—We are presuming, in answering the above questions that everything else about the plant is proportionate to the sizes given to us. We could give you a working pressure from the above particulars, but if the bolts and flanges of any of the covers or joints are relatively weak, then it would be the size of the bolts and flanges that would determine the safe working pressure and not the thickness and diameter of the cylinder or pipes. Do not forget that "The strength of a chain is its weakest link." We are therefore just answering the questions given to us and nothing must be taken for granted beyond this.

It will be understood, that in working out the strength of a cast iron cylinder, the same formula is used as that of working out the strength of a boiler shell, except that we have no seam to consider, and in the case of cast iron, the strength of material and factor of safety is different. There are quite a large number of authorities on the subject and we, therefore, think it would be a good plan to work out the strength from first principles and compare our results with the formula of some standard authority:

The formula for the strength of any cylindrical vessel is:

$$P = \frac{2t \times S}{D \times f}$$

where P = Pressure t = thickness.
S = tensile strength of material.
D = inside diameter.
f = factor of safety.

The tensile strength of cast iron is from 5 to 7 tons and since we do not know the class of material we are dealing with, for the sake of safety we had better take the least strength given. The "Practical Engineer" handbook informs us that where the load is constant, we can use a factor of 4 but if there is a variable load 8 must be used. With the above formula, using a tensile strength of 5 tons and a factor of safety of 8, we will determine the pressures.

Accumulator 4 in. dia. (inside), 2¼ in. thick:

$$P = \frac{2t \times S}{D \times f}$$

$$= \frac{2 \times 2.25 \times 5 \times 2240}{4 \times 8} = 1{,}575 \text{ lbs.}$$

Cylinder 14in. dia. (inside) 4 in. thick:

$$P = \frac{2t \times S}{D \times f}$$

$$= \frac{2 \times 4 \times 5 \times 2240}{14 \times 8} = 800 \text{ lbs.}$$

Piping .5 dia. (Bore) ⅜ in. thick:

$$P = \frac{2t \times S}{D \times f}$$

$$= \frac{2 \times .375 \times 5 \times 2240}{.5 \times 8} = 2100 \text{ lbs.}$$

It will be seen that the lowest pressure obtained from the above calculation is that of 800 lbs. for the cylinder. We will therefore check this with a formula much used in American practice, and given in Kempe's Engineer's Hand Book:

$$D = d\left(\frac{P}{f} + 1\right)$$

D = External diameter.
d = Internal diameter
P = Pressure in lbs. per sq. in.
f = 1200 for cast iron.

$$D = d\left(\frac{P}{f} + 1\right)$$

$$22 = 14\left(\frac{P}{1200} + 1\right)$$

$$\frac{22}{14} = \frac{P}{1200} + 1$$

$$P = 1200\left(\frac{22}{14} - 1\right)$$

P = 685 lbs. approx.

In this formula, however, the factor of safety has been embodied in the constant 1200 given to us, in which the factor of safety must have been a little higher than the one of 8 we used earlier. Since, however, the difference we obtain in our answers is only a matter of a difference in factors of safety used, we can take either answer to be correct, and we could think that 700 lbs. would be a reasonable pressure to operate at.—Ed.

Question:—In what proportion are dished and bumped heads on a boiler as compared to their diameter? Give a worked-out example of the formula used where no stays are required.

G. E. P.—Edmonton.

Answer:—Bumped or dished convex heads do not require staying if they are dished to a radius equal to, or less than, the diameter of the shell or drum to which they are attached.

The formula for dished heads for the province of Alberta is:

$$B = \frac{(t - 1) \times TS}{R \times 56}$$

When B = Boiler Pressure, t = thickness of the plate in sixteenths of an inch, TS = Tensile Strength of the plate per square inch, R = Radius to which head is bumped in inches, h = Camber or height of bump measured from chord in inches, C = diameter of spherical portion of head, exclusive of radius at flange in inches.

Let us suppose that the steam drum of a boiler is 36 inches dia., and the heads are made of 7/16 inch steel plate having a tensile strength of 55.000 lbs. and conform to all requirements, then

$$B = \frac{(t - 1) \times TS}{R \times 56} \quad \frac{(7 - 1) \times 55000}{36 \times 56}$$

$$= 163 \text{ lbs.}$$

Question:—In a horizontal engine running in such a direction that the crank pin is receding from the cylinder during the upper half of the revolution, which parts of the following are most affected by wear and in what manner:—Cylinder cross-head pins, guide-bars, crank-pin and eccentric sheave?

Answer:—A horizontal engine running as described would be a right-handed engine and the parts would wear as follows:—The cylinder would wear on the bottom due primarily to the weight of the piston, also to the spring in the rings. The cross-head pins would wear on the front and back sides, that is, the face nearest the cylinder cover and the one nearest the crank shaft. In each case perhaps one third of the surface of the pin would be affected or possibly less.

All the strain and wear comes on the bottom guide-bars, both on the outward and inward portion of a revolution.

If the engine was reversed, the wear would come on the upper guides. The wear on the crank-pin is usually fairly

(Continued on page 49)

Progress in New Equipment

NEW MERCURY PUMP

A new high-vacuum automatic mercury pump is described as being based on a modified Sprengel action. It works automatically, the mercury being removed from the lower to the upper reservoir, mixed with a current of dry air which is sucked through a side tube by a filter pump. The defects of design of former types of pump are discussed, their inefficiency at low pressures explained, and suitable simple remedies suggested. The introduction of an intermediate reservoir in the middle of the fall tube, kept automatically exhausted by the Sprengel action in the lower fall, allows the upper half to exert a positive exhaustion for every pellet of mercury falling down, even at the lowest obtainable pressure. The absence of compression in the first fall enables the maximum bore to be used for the fall tube; and hence speeds and efficiencies of exhaustion comparable to those of a Gaede pump are obtainable, though less than a pound of mercury is required to operate the pump.

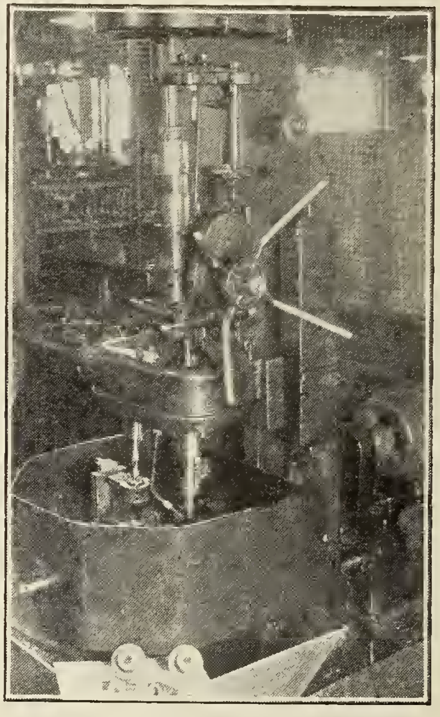
A VALVELESS PUMP

Every user of a reciprocating pump knows the endless trouble which arises in connection with the valves. However carefully these are designed and however well they are manufactured, they sooner or later require replacing or repairing owing to the heavy strain which is placed on them. With these difficulties in view countless inventors have tried to make a reciprocating pump without valves; but complete success seems to have been reserved for a British engineer. His pump has no valves and is so constructed that its cylinders fill and discharge completely on every stroke thus giving the highest possible efficiency. The only parts liable to repair of replacement are those employed in the driving head and they are all easily accessible and are standardized so that they can be rapidly interchanged at slight cost. The materials used are specially selected to ensure the maximum of wear. During a test recently carried out on a six-inch pump driven by a one horse-power motor 5,000 gallons of water were pumped per hour against a head of about six feet.

L'Air Liquide Society announce that, in future, their products will be sold by the Canadian Liquid Air Co., who will retain the sales offices and staff of the former and assume all contracts.

DRILL ADAPTED TO SPECIAL OPERATION

An interesting drilling and reaming operation on a regular Rockford 20 in. box column drilling machine is shown in the accompanying illustration and described herewith. The drill is regularly rated as having a capacity to drive a 2 in. high speed drill in solid steel. The drive is direct by silent chain from electric motor through interchangeable pick-off gears for speed changes. Four speed changes are regularly provided in a simple feed box.



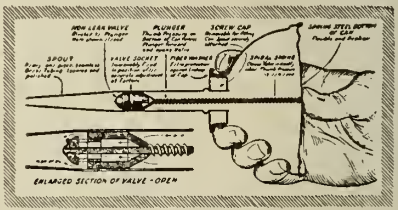
Interesting drilling and reaming operation.

A four station rotary table, with index plunger worked by foot treadle, is applied to the regular table. The rotary table is indexed by hand after the locating plunger is pulled. The table is provided with four two-jaw chucks, with formed jaws to suit the work. An extended wrench is provided so that the work of tightening the chuck screws takes place outside of the chip guard. These chucks are under work spindles with operation going on while the fourth is being loaded. A finished piece is removed at each index. A three spindle drive head equipped with a "V" gibbed slide, is mounted on the table ways. The spindle drives and feeds this head. The head is fully-counter weighted. A positive micrometer adjustment stop on the quill is provided for a depth gauge. An adjustment for height and diameter of drill; drill bushings support is provided under the left hand spindle.

The sequence of operations is given as follows: first spindle, rough drill; second spindle, rough taper ream and face; third spindle, finish taper ream. The work consists of yoke and flange members of a new oil lubricator universal joint, and production is maintained at the rate of 250 pieces a day. Diameter of rough drilled hole, ¾ in., length 2⅝ in.

NON-LEAK OIL CAN

An oil can that is constructed to prevent the dripping of oil from the spout except when pressure is applied to the spring bottom has recently been placed on the market. The valve socket is located in the spout of the can and rigidly fixed in a definite position after accurate adjustment at the factory. The valve that regulates the flow of oil from the can is riveted to the plunger that extends from the valve to the spring bottom of the can. Pressure on the can bottom forces the plunger outwards and opens the valve in the spout. A small spiral spring surrounding the plunger causes the valve to close instantly when thumb pressure is removed. The spout is drawn from the best quality brass and will not bend, turn or split. The can is made of rolled steel, copperized inside and out. The screw cap is particularly large and a fibre washer provides extra protection against leakage. All cans are tested at 110 lbs. air pressure. They are known as the "O-NO-DRIP" and are made by Arthur S. Harding Co., Boston, Mass.



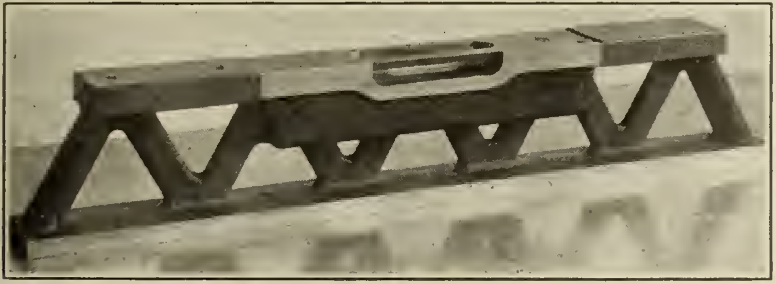
O-No-Drip Oil Can.

AN IMPROVED GAS PRODUCER

When power has to be produced at an isolated point where a waterfall is not available, one of the most economical sources is the gas producer. This appliance practically distils coal by a continuous process of air suction through the burning fuel, but most of the forms hitherto designed are open to serious objections in practice. The main difficulty is to produce a steady flow of gas of uniform quality from a producer which has to be fed intermittently. A recent type of producer developed in Great Britain obviates this drawback by arranging that the feeding of coal shall be continuous and that the fire-bed itself will be agitated so as to keep the process of distillation going ahead continuously. These improvements have now been combined with an ash extractor of novel and ingenious design. It is essential that the ashes shall be removed evenly from all parts of the ash bed continuously; and in the new producer this effect is obtained by means of a beam which revolves steadily and is provided with teeth which project upwards and forwards through the ashes. At each end there are six scoops arranged on a rotating ring, and each scoop as it revolves removes a certain quantity of the ashes forced out by the teeth already mentioned. Tests show greatly improved results over the usual type of gas producer.

TRUSSED FRAME PRECISION LEVEL

A precision level of extreme accuracy has recently been developed and placed on the market. These levels can be made with different degrees of sensitiveness but the one generally used is the 10-second instrument. With this level each division (1/10in.) that the bubble runs indicates a variation from the horizontal of .0005in. in one foot. From this reading the necessary adjustment can be readily made. A 10-second level has a vial ground to a radius of curvature of about 170 feet and is as sensitive as is found practicable for setting up fine machine tools and similar work. A 3-second level having a proportionately larger radius of curvature is more sensitive but requires several minutes for the bubble to come to rest. Levels more sensitive than 10-seconds are too sluggish for shop use.



Trussed frame precision level.

The inside of the vials used in these levels is ground with extreme accuracy to a uniform curvature and they are carefully inspected to make certain that each division indicates the same angle of inclination. This assures the accuracy of the instrument and is also particularly important in its adjustment. The frame is 15 in. long, experience having shown that a frame of this length, used with a straight edge when necessary, is more convenient and reliable than a longer one. The trussed construction not only makes the frame light, rigid and convenient to handle but also renders it comparatively insensitive to temperature changes. Insulating grips make it unnecessary to touch the frame when handling, thus eliminating possible errors due to expansion from the heat of the hands. These levels are made by the Pratt and Whitney Co., Hartford, Conn.

NEW RECIPROCATING PUMP

The Pulsometer Engineering Company, Reading, Eng., have just placed on the market a new model of a pump of the reciprocating type, which is stated to combine high efficiency with silence, compactness, and light weight. The pump is of the single-acting plunger type, fitted with patent rubber ring valves both for suction and delivery. The driving drum is arranged for connection with any convenient source of power to run the pump at 300-500 revolutions per minute. As the valves are made of rubber, and only a slight movement of this material is necessary, the pump is said to work absolutely silently. Automatic lubrication makes it possible to run the pump for long periods without skilled attention and, the moving parts being entirely enclosed, it is possible for the pump to be placed in a private house without it being a nuisance to the inhabitants either from its noise or uncleanliness. This pump is made in four sizes, ranging in capacity from 250-2,000 Imperial gallons per hour to work against heads of up to 100 feet.

Magnetic chucks are very efficient for holding small pieces for grinding, as the entire face of the chuck can be covered with such parts, thereby supporting each other firmly, so that a large number can be machined at one time, resulting in a much larger production than would be possible by handling the pieces separately.

ELECTRIC CHAIN HOIST

An electrically operated material handling hoist intended for service in places where the travelling crane or the hand hoist would not be convenient or economical, has been placed on the market recently. The hoist may be transported to any desired location and easily erected for temporary services. The apparatus consists of a standard chain hoist modified in design to be operated by a small heavy-duty motor, which drives the chain block by means of reduction gearing and a slip friction clutch; all this mechanism is mounted on a malleable iron supporting bracket. While the electric-driven hoists are regularly furnished as complete units, the motor attachment is so designed as to be readily fitted to existing chain hoists. In the event of stoppage of electric power the hoist can be operated by hand in the usual manner. The devices are made in sizes to be applied to hoists ranging from 1-4 to 10 tons capacity. The armature shaft and driving worm are supported in heavy-duty ball bearings and ample provision is made for adequate automatic lubrication. Only one hand is required to operate the pendant controller, the other one being free to steady and guide the load. Strength and lightness are features of construction. The weight of a one-ton hoist will be approximately 148 lbs. These electric chain blocks are made by the Motorbloc Corporation, Summerdale, Philadelphia, Pa.

IMPROVED FORM OF PULLEY

No kind of equipment is more familiar to the engineer than a shaft carrying pulleys; and in most cases it retains a primitive simplicity which makes it adaptable to a wide range of conditions. There are, however, cases where a departure from the traditional form is likely to be advantageous. For example, the development of ball bearings, to which keen attention is being given in Great Britain, is regarded as an important source of economy in running. Another feature is the use of a split pulley where it is necessary to add pulleys to a line of shafting. Quite a new form of split pulley, claiming many advantages, has been introduced by a British firm, and it is so simple in construction that one person can easily mount it on a pulley within a minute. The pulley is made in two parts, one forming more than three-quarters of the circle and carrying two projections against which the other piece is fitted. The adjustment of one screw tightens up the pulley and keeps it in straight alignment. No side-holding screws are employed, so that the pulley can be fitted close up to another pulley. This and its other advantages make it peculiarly well suited for experimental work where pulleys have to be put on and taken off with the least possible interruption of other work.

Electrical Section

TO PERMIT a dynamo to generate electricity, it is necessary that a magnetic field be supplied, also that a conductor consisting of a loop of wire should move across this magnetic field in such a manner that the number of magnetic lines of force due to this magnetic field, passing through this loop should be changed. It is in this act of changing the number of lines of force through the loop which results in the dynamo generating electricity.

Strictly speaking, the dynamo does not generate or create an electric current. The action of the dynamo is really similar to that of a pump connected to a well. The water is already in the well, the pump does not create the water, it simply produces the water at the location required, by lifting it out of the well.

The dynamo simply disturbs the balance which exists between Nature's supply of positive and negative potential existing in all space. The dynamo therefore simply creates this difference of potential by virtue of which a flow of current is enabled to take place.

It was found by experiment that the most convenient method by which to achieve this changing of the number of lines of force passing through a loop of wire, was to arrange such loops of wire in such a manner that they could be rotated between the poles of a magnet. This when completed was known as an armature. Such an armature may be made of any material sufficiently rigid to withstand the centrifugal force when given a rotary motion. It is merely a form upon, which to mount the necessary loops of wire. In practice, however, the armature core is always made of metal and should be made from the finest charcoal iron. The reason why it is made of iron instead of wood or some fibrous material, is entirely due to the fact that the magnetic field is intensified by the iron, in a similar manner to the effect of inserting a piece of iron into a solenoid (as explained in one of the earlier articles).

When dynamos were first made, the armature cores were made in one solid piece, and slots cut into the core to accommodate the turns of wire round the core. It was found however that all such armatures rapidly became hot, when placed in operation.

This phenomenon was due to what is termed eddy-currents. Upon devoting a little thought to this matter we soon realize how these eddy currents are generated. We wind our loop of wire along the length of the armature (so that it will face the full width of the pole piece face) and it has induced into it, a current of electricity. Therefore it is only a logical conclusion that the larger mass of metal forming the armature core, should also have a current induced in it. Furthermore, on account of its relatively large mass, its resistance will be less than that of a small conductor resting on its surface, therefore in accordance with Ohms Law, quite a small electro-motive force will be capable of circulating quite a large current through this mass and as the heating effect of a current of electricity is proportional to the current squared multiplied by the resistance, it will be apparent how soon this may reach rather large proportions.

The heating effect was also found to be very detrimental, since not only was the effect on the core to be considered, but there was the effect on the insulation of the wire forming the winding of the armature, and furthermore, there was the waste of energy in driving power. As we cannot get something for nothing, this heat energy was naturally only derived from some form of energy supplied to the mass, and this was the energy applied in causing the rotation.

The solution naturally was in reducing the mass through which these eddy-currents flowed. This could be readily effected by dividing the armature core into several sections, and insulating each section from its neighbour. The eddy-current loss is proportional to the thickness of the armature core. Obviously therefore if we make the core entirely out of very thin discs, we will reduce the eddy-current loss to a minimum. To achieve this object laminated armatures were introduced. The lamination of an armature is always carried out in a plane at right-angles to the direction in which the eddy-currents would have a tendency to flow.

The armature is built up of thin laminations or core discs not more than 1/32 of an inch in thickness, the best quality of iron only being employed for this purpose. These laminations being stamped out in the form of the finished section of the armature, they are then bolted together or keyed on the armature shaft. Generally the oxidised surfaces of the thin discs are sufficient to introduce a high electrical resistance, and so cut down the flow of current to a minimum. Frequently, however, they are given a coating of varnish, whilst in special cases, very thin sheets of paper are pasted on the surface of the discs. The resistance so built up, will be sufficient to successfully oppose the small potential difference which arises between one disc and the next, and thereby prevent any serious flow of eddy-currents.

The designs of these armatures vary considerably as will be seen from the list of the following types here given: "Siemens," tripolar, quadripolar, plain ring, slotted ring, plain drums, slotted drum, tunnel, and multipolar.

The Siemens or H armature, is now obsolete, so far as large modern construction is concerned, but is still used for toy dynamos and motors and also ignition, and telephone magnetoes. Upon considering this type it will be apparent that the conductors are spaced a full 180 degrees apart. This will mean in the case of a dynamo possessing only two pole pieces, that there will be a very great fluctuation in voltage each revolution.

The tripolar armature is an improvement on the H type on account of the conductors being spaced 120 degrees, with a consequent steadying of the voltage. By increasing the number of slots

TYPES OF ARMATURE LAMINATIONS

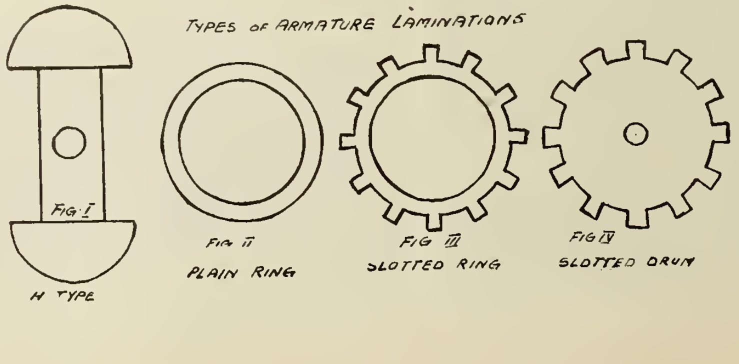


FIG I — H TYPE

FIG II — PLAIN RING

FIG III — SLOTTED RING

FIG IV — SLOTTED DRUM

round the disc, we obtain a spacing for the conductors, which permits a greater number of series conductors, and as one conductor leaves the densest part of the magnet field another so quickly takes its place, that the momentary fluctuation of the voltage becomes less and less perceptible.

The plain-ring armature is perhaps the easiest of all types to wind, the slotted-ring being only a modification of the plain-ring type, therefore the same remarks apply. It has certain special characteristics which are somewhat of an advantage, the principal one being its entire absence from local vibrations due to the magnetic lines which gather in tufts on all armatures that have a number of tooth like projections. However, its other faults weigh seriously against it, so it is no longer employed.

The slotted-drum is the type most frequently employed, and is the one most frequently to be met with in actual practice.

We are now in a position to consider the methods employed in winding the conductors, or inductors on to the armature core. It is important at this stage to fully consider again a few of the calculations concerning series and parallel circuits, dealt with in articles that appeared in this paper in February and March 1922. By once again reading the articles referred to the subject will be refreshed in the reader's mind. The necessity for the reconsideration of this subject is due to the fact that on all armatures in practical application, there are certain conductors that are in series throughout the winding, whilst others are in parallel, and it is the combination of these parallel windings which has to be taken into consideration when arriving at the fundamental equation for the generation of the voltage of the dynamo. Furthermore, the capacity of the dynamo in amperes is governed by the sectional area of the conductors and the number of conductors in parallel.

For some strange reason or other, this subject of armature winding has become shrouded with an atmosphere of mystery, and plant engineers have permitted themselves to become scared at the thoughts of any attempt at winding an armature which has broken down. All modern armatures have a closed circuit system of windings, which means that the current after circulating through the whole of the windings; comes back to the starting point again. The simplest way to approach this subject is to consider the armature to be cut open and spread out flat, which gives what is known as the developed system. It is possible then to see just where each loop of wire goes to, and where it takes its bend at the back end of the armature.

To avoid the complications of having too great a number of lines on the sketch it is much simpler to follow, if each slot in the armature is only supposed to contain one conductor. It will be observed that a certain length of wire is required to make the connection to the commutator, and that length of wire is outside the face of the pole pieces. This does not affect the electrical continuity of the circuit, as the current has already been induced in the coil and will flow round it and down on to the commutator, and from there be picked up by the brushes. In fact the commutator forms an excellent medium for making a good joint, as it should always be so arranged that there are no joints along the loop of wire forming the inductor.

By following the arrows round each circuit shown on the armatures in Fig. 5 and Fig. 6 it will readily be seen how the current circulates through the whole set of windings, coming back to the place from whence it started. In the sketches, only one coil in each winding has been shown to permit of the subject being more readily understood. In actual practice, however, several coils would be included in each sector of the armature but this makes no difference to the pathway of the current, since it would merely go round and round in that particular sector, the number of times that there were number of turns. It would then pass on to the next coil in series and again round and round as before, but there would only be two ends to each coil, no matter how many turns comprised the coil, one end would start the coil and the other would terminate it.

In Fig. 7 there is shown a sketch of a 12 slot-drum-armature, and a 12 segment-commutator. It is easy to see at a glance in this figure the active conductors as represented for an armature to revolve within a 2 pole field. It will also be noticed that the span of the armature coil is just one half of the circle, or in other words, covers 180 degrees. This is because each coil must be so spaced that it covers the face of the pole-piece when it is present to the pole. In other words, as one side of the coil is under the one edge of the pole piece, the other side of the coil should just be under the other edge of the opposite pole piece. Opposite sides of the same armature coil must always lie under poles of opposite polarity. This is the reason why a 2-pole armature will not work if placed in a dynamo which possesses a 4-pole field.

In the case of the armature shown in Fig. 7, if we wished to make this suitable for running in a 4-pole field instead of a 2-pole, we would have to strip the armature and arrange the span of the coils to meet the new conditions. Since opposite sides of the coils must be under opposite pole pieces, and as we have now 4 pole pieces spaced 90 degrees apart, we need to divide the armature into 4 sectors of 90 degrees each, and relay the coils in the slots falling within each of these sectors. See Fig. 8.

It will be obvious that each coil performs its own little function in having a current induced into it as it passes under the influence of each magnetic pole. Such a current will be of a certain voltage, but the voltages now called for are higher than can be commercially obtained by several coils in one slot of the armature, therefore we need to connect a certain number of the coils together in series, and so augment their voltages until for a given speed we can obtain voltages in the nature of 250 to 500 as is now generally demanded.

Both ends of the coil on the armature must be connected to the commutator, and for convenience the segment on the commutator nearest to the free end of the coil may be used for the first connection, but the other end of that particular coil must have sufficient length to reach back to the segment of commutator next to the segment to which the beginning of the coil is connected. This is known as the "step" of the commutator.

There are two distinct methods of applying the winding to the armature core, one is by hand winding, and the other is former winding. The hand-wound armature is now only used in the case of very small machines, in all other cases former winding is generally used.

Former winding is much more symmetrical in appearance, and is far easier to ensure good insulations between the coils, as the coils are wound on wooden shapes or "formers." These are then varnished, taped and snugly fitted and shaped to their final position without the forcing and crushing of the insulation which frequently results from trying to wind the coil smoothly and tightly in the case of hand winding. Furthermore, portions which are at the maximum potential difference are brought close together, and there is apt to be difference in respective lengths of the coils, leading to unequal resistance. This would cause a difference in current values, with a resulting difference in armature reaction, which again results in troubles in obtaining sparkless commutation. However, as they are much

Operators' Point of View

OIL VERSUS COAL

R. M. McLaren

Being slightly interested in the relative values of oil and coal as fuel, I collected some data based on the experience of several users of oil. In one plant I was told that an evaporation of 14 lbs. of water was obtained with oil. The evaporation with coal was not given, but Chas. C. Moore & Co. credit oil with an efficiency on an evaporation basis of 4 per cent. better than coal. This is undoubtedly on the assumption that both coal and oil plants are good. The comparison of a good oil plant with a poor coal plant would be unfair and the comparison of a good coal plant with a poor oil plant would also be unfair. We may also assume that they have taken a stoker-fired plant as the basis for their comparison and that a stoker plant will have 5 per cent. better efficiency than hand firing. As I wished to compare oil-burning with hand-firing we will have to allow an advantage of 9 per cent. to oil.

The evaporation of 14 lbs. of water would require 14 x 970=13,580 B.t.u. (Marks gives 970.4 as the latent heat of steam). This gives an efficiency of

$$\frac{13580}{19000}=71.5$$

almost, assuming that the oil has a B. t.u. value of 19,000. The specific gravity of fuel, or reduced oil is about .9 and at 9 cts. per gal. the price per lb. would be 1 ct. The efficiency of the coal plant would be 71.5—9=62.5 per cent. and assuming that the coal has a heating value of 13,000 B.t.u. there would be transmitted to the water

$$\frac{13,000 \times 62.5}{100}=8,125 \text{ B.t.u.}$$

Coal at $9. per ton=9/20 cts. so that for one cent we would get 20/9x8,125=18,055 B.t.u.'s transmitted to the water.

We all see that in buying coal we get

$$\frac{18,055 \times 100}{13,580}-100=$$

33 per cent. more for our money on the basis of evaporation than we do when we buy oil. There are charges to be added to the cost of coal for handling, storage, etc., but there are charges to be added to the cost of oil also for boiler room attendance, atomizing (when steam is used), etc., so that I don't see how it is possible to add 1/3 to the cost of coal. The saving in labor depends on the size of the plant and unless the plant has at least ten boilers in operation it is impossible to realize the best possible saving in labor.

In another plant the evaporation was given as 13.7 lbs. This was another win for coal.

In another plant an evaporation of 15.2 lbs. under test conditions was claimed. This is a little more than 8 per cent. better than 14 lbs. and the owners of the plant admitted that they were not using oil because it was cheaper. (They admitted that it cost more to use coal and for other reasons.)

In some plants it was not known what the evaporation was, so they made the comparison on the basis of the annual fuel bills, a rather crude and common basis, or perhaps they liked oil. The annual fuel bill basis is crude because the climate affects the demand for heat, although some will say that it takes just as much fuel in mild weather as it does in cold. I wonder if such people run their heating plants in summer and if they don't, why not?

In one plant it was claimed that 85 gals. of oil was equivalent to 1 ton of coal, and this the best anthracite. This looked good, so some figuring was done. Now 85 gallons of oil would contain 85 x 9 x 19,000=14,535,000 B.t.u. and allowing an efficiency of 75 per cent. for oil, there would be

$$\frac{14,535,000 \times 75}{100}=10,901,250$$

B.t.u. transmitted to the water. This is also the amount of heat transmitted from a ton of coal to the water. Assuming that the heating value of the best anthracite is 13,200 B.t.u., there would be in 1 ton of coal 13,200 x 2,000=26,400,000 B.t.u. As 10,901,250 B.t.u.'s are transmitted to the water the efficiency of the coal plant must have been

$$\frac{1,901,250}{26,400,000}\times100=41.3$$

per cent. or nearly. This is efficiency that very few of us would be proud of. But there may be another reason why 85 gallons of oil is the equivalent of one ton of coal and it may be the high price of the coal. It will be seen that 10,901,250 B.t.u.'s are transmitted to the water. This must also be the amount of heat in the coal transmitted to the water. The coal plant was assumed to be 66 per cent. efficient, so the total heat in the coal must have been

$$\frac{100}{66}\times10,901,250=16,517,000$$

B.t.u.'s, about. This amount of coal cost the same as 85 gallons of oil, or $7.65, so 264,000,000 B.t.u.'s, or one ton of coal must have cost

$$\frac{26,400,000}{16,517,000}\times765=\$12.23.$$

It doesn't look quite fair to ask us to believe that 85 gallons of oil is the equivalent of a ton of coal without telling us why. "Caveat Emptor" may be good law but it is not good justice. However there are places where law is in the ascendancy over justice. The problem may be clearer to some when it is explained that 16,517,000 B.t.u. is the heat value of 1,251 lbs. of coal, that is

$$\frac{16,517,000}{13,200}$$

A claim that is frequently made for oil is, that the efficiency may be or is maintained at a higher level than it is with coal. While it is possible to do so, no doubt, it was found that it was not always done. I found this out when I discovered that in a plant that got an evaporation of over 15 lbs. under test conditions, it slumped to about 10.5 lbs. for a week's run. This is not very complimentary to oil. Coal could hardly do worse.

In conclusion I would like to call the attention of a gentleman named Shovel to a slip he made in Power House, Nov. 20. Mr. Shovel bases his calculation on oil weighing 10 lbs. per gallon. This is hardly correct. Mr. Shovel also gives 7 cts. per gallon as the price of oil. This looks rather low, but perhaps Mr. Shovel lives in an oil country.

BENEFIT FROM POWER HOUSE

Editor, Power House:—

As a reader of Power House I desire to express a word of appreciation for the way in which our late editor, T. H. Fenner has labored to assist the stationary engineer in his struggle to mount the ladder of progress.

I myself have derived much benefit from his teachings, having gained considerable knowledge on engineering subjects both through P. H. and his teachings elsewhere. Great credit must be given Mr. Fenner for the able and practical manner in which he conducted the "Question Box," for this department could not have been other than of great assistance to all readers of Power House. I for one am guilty of taking considerable time of our late editor through that department.

There may be others at present writing in the same tone as I, but if not, I am sure that there are hundreds who are thinking the same and are appreciative for the knowledge they have gained through P. H. during Mr. Fenner's editorship.

I am glad to learn that he is not leaving our midst but that we shall see him occasionally.

The least that we can do is to wish him every success in his new sphere of endeavor.

E. G., Toronto.

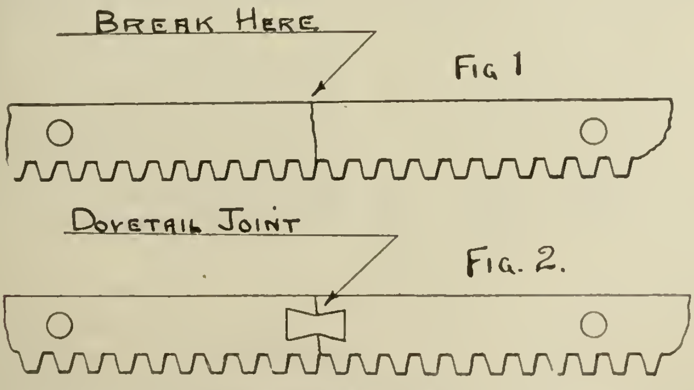
MARINE BOILERS FOR LAND STATIONS

During the war many important advances were made in the design of the boilers fitted to British men-of-war. The exraordinarily severe service demanded from naval boilers stimulated invention in many directions. The reduction since the war in naval programmes of all nations has accordingly restricted the demand for such boilers, and the makers are turning their attention to other fields. They have found a very promising one in the electric pump station. The marine type of boiler has the advantage of taking up comparatively little space and of being able to give a very rapid increase in steaming power, when, for example, a sudden load comes on the station. In one large British electrical station two of these boilers are being fitted with oil burners, and excellent results are expected to follow.

"REPAIRING A BROKEN RACK"

By G. Blake

This was a small mild steel rack, which had broken as shown in Fig. 1. As it was not possible to cut another, the writer repaired the broken one as shown in Fig. 2. Two dovetail slots were cut, one in each of the broken ends, and a dovetail wedge piece was snugly fitted. The slots were given a slight taper or bevel so that when the rack was brazed the molten metal would flow into the bevelled slots and make a solid joint. Regarding the brazing, it may be mentioned that to ensure the rack being straight, and to prevent any warping it was supported on a cast iron slab on two thin parallels near to the joint and held in that position by two small clamps during the brazing operation. This repair turned out entirely successful, and much time was thereby saved by repairing the broken rack, as to get another from the makers would have taken nearly a week.

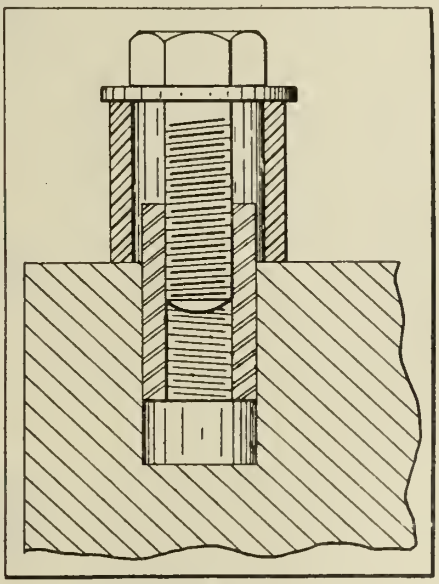


Repairs to Machine Rack.

REMOVING BUSHINGS

By A. Le Marshall

A method which the writer has used for a number of years in removing bushings from blind holes, and one that has given good satisfaction, is to run a tap of the nearest size into the hole of the bush so that a shallow thread will result. By placing a sleeve, a little larger than the bush, over the opening and using a washer and cap screw as shown in the sketch, the bush can be drawn out quite easily. This method will be found useful in automobile work, where the through hole is a trifle larger than the inside diameter of the bush. The writer has used this method in removing hardened bushings from air hammers. First plug the hole with fire clay to keep flame out of cylinder then heat and anneal bush, after which tap and draw out as stated.



Removing tight bushings.

QUESTION BOX

(Continued from page 43)

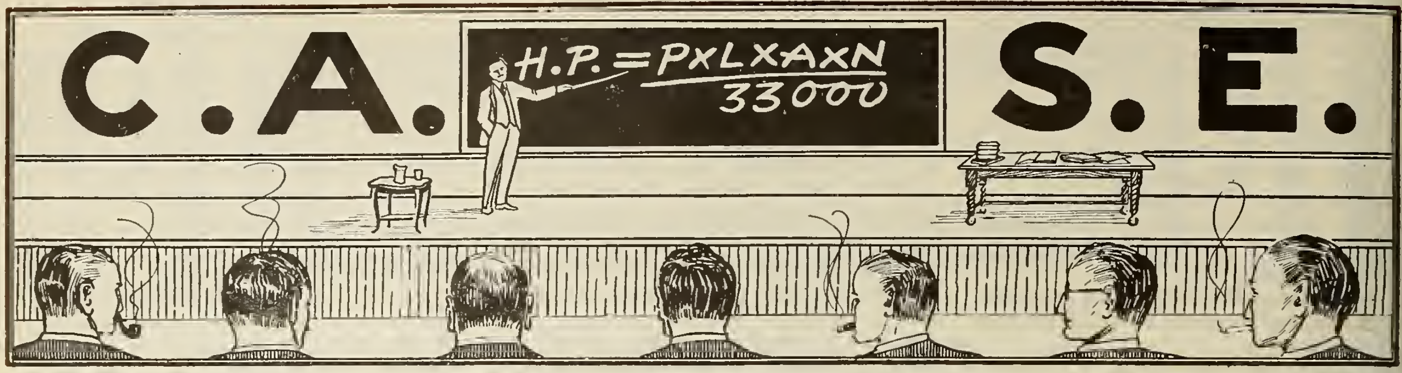
uniform, although if great accuracy was needed, it would be found that it wears slightly more at the point of greatest effort, that is, when the crank in nearly on the top and bottom of its path, or the cross-head is about mid-position. On account of the pressure being greatest at this point, the friction of the brass has the greatest wearing effect upon the pin. This last remark would also apply to the action of the strap and sheave of the eccentric, although the point of greatest effort, in this case would be when there was the greatest resistance due to friction on the valve face. The thrust or wear on the guide of the valve spindle would be directly opposite to that of the cross-head guides. An article will shortly appear in Power House dealing with the question you raise in respect to the length of connection rods and valve spindles.—Ed.

Question:—In a battery containing four boilers having the feed water pipes connected to one common header, it is found that whilst the boilers are in operation, the water gets too high in some boilers and too low in others, even when all the feed regulating valves are fully opened. It is also noticed that the same boilers are differently affected at different times. State the probable causes and methods of remedying this.

J. K.—Fernie.

Answer:—We are afraid J. K. is having a trouble that is very often experienced in a boiler room, especially where there are a large number of boilers and the boiler house is on an exposed position. There is, however, no mystery about such a condition. It simply means, that if the feed water is actually being pumped into the boiler, and the water level is falling, if there are no holes in the bottom of your boiler, the water is actually being evaporated. I have seen the same condition on numereous occasions, and in some cases it has been found that a change in the direction of the wind has had some effect upon it. It would be a good idea to keep a record of weather conditions the next time this occurs and by careful observation, you may possibly trace the origin to some such cause. It would be advisable to examine your brickwork dampers and baffles (if boilers are of the W. T. type) first and make sure everything is in good condition and tight.—Ed.

Winnipeg.—A terminal elevator with a capacity of 1,500,000 bushels will, it is reported, be erected at Port Arthur by James Stewart, president of the Maple Leaf Flour Mills, according to authoritative information obtained here. The cost will approximate $850,000 and construction will be commenced during the forthcoming winter. The site selected is near Thunder Bay elevator.



THE program for 1923 is herewith produced for the benefit of new subscribers to Power House. The complete program was dealt with in Power House issue of Aug. 20, 1922.

1923 Educational Program

January—First meeting: Boiler Room Appliances. Second meeting: Makes and Types of Feed Water Pumps.

February—First meeting: Miscellaneous Auxiliary Appliances for Boiler and Engine Room. Second meeting: Types and Makes of Steam Engines in Use.

March—First meeting: Indicating and Recording Meters—Their Types and Make. Second meeting: Indicating and Recording Instruments For Pressure and Vacuum.

April—First meeting: Boiler Room Efficiencies and How Determined. Second meeting: Engine Room Efficiencies and How Determined.

May—First meeting: Report Forms and Records. Second meeting: Useful Formula and Data.

The general education committee of the C. A. S. E. have entered the second section of their program for the season of 1922-1923. During the 1921-1922 season there was but one subject scheduled for each month, but this present season has seen a more intensive program arranged, there being two subjects, one for each meeting during the month. The different branches of the C. A. S. E. have been doing good work in connection with educational lines and no doubt more engineers will avail themselves of this splendid opportunity for education in the future.

Montreal.—There has been a rumor for some time that the Montreal branch of the C. A. S. E. are considering the formation of a separate organization, to be known as the Montreal and Quebec Province Educational Association. This is unfortunate, both for the C. A. S. E. and the Montreal branch. In view of the fact that the honors of grand president are now held by one of their illustrious members, they should hesitate to do anything that would tend to arrest the good work done by him in the past.

Although he was not one of the original incorporators, Henry Wright, chief engineer of the Hochelaga power plant of the Montreal Tramways, has done more than any other engineer to steer the C. A. S. E. "barque" in the right course. In fact, the splendid and unselfish work done by him both personally and by arduous correspondence with all the various provinces in the interest of the C. A. S. E. makes him well deserving of all the honors which could be given him not only by the C. A. S. E. but by all operating engineers. Mr. Wright is himself an honor and a credit to the association, being a member of both the American and Canadian associations of mechanical engineers. Besides encouraging the C. A. S. E., he has been instructing classes in engineering both in the C. A. S. E. and Y. M. C. A. Mr. Wright was the pioneer and most enthusiastic supporter of the Dominion-wide certificate with a uniform and standard form of examination, and his ambition can best be accomplished through a national organization such as the C. A. S. E.

There may have been some dissatisfaction with last year's educational program, and possibly some feeling about the present rules of government. However, these can all be eliminated and a broader and better one substituted. If Montreal contemplates something better then the engineers from coast to coast should have the benefit of it. Stick by the old ship C. A. S. E.

Toronto.—No. 1 C. A. S. E. held their regular meeting from 8 to 11 p. m. Jan. 16. It was a very stormy night in more ways than one. However, in spite of it being the coldest night of the year, quite a few remained to attend the educational program which was put on by R. McLaren, the chief engineer of the Massey-Harris Co. The subject was Feed Pumps and Their Various Types and Makes. Mr. McLaren read a paper on the subject and also made graphic illustrations on a large blackboard in connection with his paper. The whole lecture was listened to with very great interest.

As a result of the intensive educational campaign put on by Toronto No. 1, also the special interest taken by the newer members, a large increase in membership is looked for in the near future.

The subject for discussion at the next meeting of the C. A. S. E. will be: Various Types and Makes of Circulating Pumps. Papers are invited from members and "adherents."

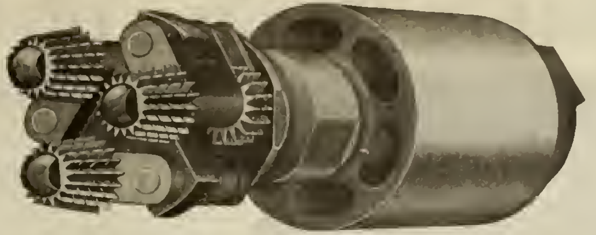
The friends of G. A. Brown, the recording secretary of Toronto No. 1, C. A. S. E., will be glad to know that he has fully recovered from his recent illness.

Split Bearings

Difficulty.—Small two-part split bearings made out of lead-base babbitt have a spongy surface on shaft bearing part. Heating of shells, mandrels and babbitt being correct. **Remedy.**—This is due to the fact that the shells have been poured with their mandrels on top, thus allowing a certain amount of dross to fill up the part of shell in contact with the revolving shaft; a lead-base alloy generally has more dross to it than a tin-base one. These small two-part bearings are best poured in a horizontal position, bottom upwards (which causes any dross to rise to the top and makes it stay next to the bottom of the shell when casting is done), the mandrel resting on a surface plate and the molten metal poured through holes in the bottom of shells. This method of working has the great advantage of making the bearing surface very clean and dense, the babbitt is compressed by the weight of metal on its top, which faces the bottom of shells, an impurities or dross thus remaining bottom part of the finished casting

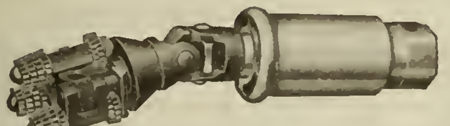
In the pouring of large 2-part bearings using the same quality lead-base alloy, as in the small bearings listed above, it is much better practice in order to get sound castings, to have the shell and mandrel in a vertical position, the front bearing surface facing downwards. This causes any dross that will form to rise to the back end of the casting part which faces toward a shaft's end so that there will be a thin layer of dross that can be cut off if proper allowance has been made for extra metal. These large bearings can also be cast bottom upwards like the small two-part ones, but, as a general rule, it will be found much more convenient to do this pouring with the shells in a vertical position.

Amherst, N.S:—A preliminary survey has been completed by the Nova Scotia Power Commission with reference to their projected power development scheme on the Economy River.



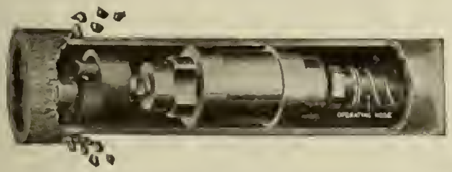
Standard Water Driven Tube Cleaner

KEEP YOUR BOILERS CLEAN



Lagonda Water Driven Cleaner for Curved Tubes

Lagonda Air Driven Cleaner for Straight Water Tubes



Cleaner Removing Scale from Outside of Fire Tube

All natural waters contain some impurities which, when introduced into a boiler, may appear as solids deposited on the heating surface. No matter what the substance consists of, it must be removed at frequent intervals or it will decrease the capacity and efficiency of the boiler and may cause it to be badly damaged by over-heating.

Some waters, notably well waters, deposit such quantities of scale that they should be purified before going into the boiler, thereby preventing an accumulation of incrustation and consequent damage to boiler parts, and at the same time effecting a large saving in fuel by keeping all parts of the heating surface in a clean and efficient condition. If you have bad feed water it is a case for the chemist, for the scale is probably composed of several substances which must be known before the exact treatments necessary to get rid of them can be determined upon. The use of treatment without technical advice is poor policy.

Stony and vegetable matter in suspension can be removed by FILTERS, which we supply in various sizes and designs to suit all requirements. In most Canadian plants, lake or river water is used for feed, and these waters seldom carry large quantities of scale-forming materials in solution. Scale can be allowed to form in boiler for a considerable period. Experience in each individual plant determines the limit at which tube difficulties will begin or a perceptible falling off in efficiency will take place. With such a limit of scale formation fixed, and the danger of allowing it to be exceeded, well understood, probably the most economical and efficient method of keeping the heating surfaces clean is by use of the LAGONDA TUBE CLEANERS.

The cleaners are designed and so constructed as to thoroughly remove all the scale, in the shortest possible time, at the lowest cost of operation, and they require a minimum amount of repairs, reducing both the waste boiler time and labor cost of cleaning.

They are made to operate by either water, air or steam. In every case a swing head is furnished so designed that three sets of cutters are thrown out by centrifugal force against the scale in such a manner that they make straight line contact with the tube and they do the work without damage to it.

You can be supplied with LAGONDA tools for cleaning Economizers, Condensers, Evaporators and other tubular plant.

We shall be very glad to furnish full particulars

BABCOCK & WILCOX, LIMITED

TORONTO OFFICE, BANK OF HAMILTON BUILDING

A Reasonable Saving of 5 to 10%

Should You Expect More?

WE GUARANTEE that with the use of CYCLONE SHAKING AND DUMPING GRATE any grade of hard or soft coal, or screenings of same, can be burned with excellent results both as regards Economy and Capacity; that the total annual expense to the user for coal, interest, depreciation, repairs, damage to boiler, liability of shut-down, etc., will be much less than would be the case with any other type of Grate or Stoker on the market.

The Canadian Steam Boiler Equipment Co., Ltd.
Sole Makers for Canada
20 McGee St. PHONE G. 3660 Toronto, Ont.

ELECTRICAL SECTION

(Continued from page 47)

easier and quicker to manufacture, and since all coils in any given armature will have the same displacement, throw or pitch, one former would be sufficient upon which to form the shape of the desired coil. Furthermore, on account of each coil being quite symmetrical there is no tendency to unbalanced voltages due to the difference of self-induction. Therefore all the evidence is in favor of the coils being former wound, especially when we consider how they simplify the actual operation of winding. Again the coils built on a former have been made to the exact "pitch" of the armature and as the coils are bound to be correctly spaced they will fit snugly in the slot to which its "pitch" conforms. This should fit without much strain or forcing and the edge of the coil just be sufficiently short to make the fitting "friction tight."

Largest aluminum casting ever made in United States was cast at plant of Light Mfg. and Foundry Co., Pottstown, N. J. It weighs 1,275 pounds, five feet high and eight feet long and was cast for a printing press concern at Dunellen, N. J.

Montreal.—The new foundry of the G. & J. Weir Co., Ltd., at Ville St. Pierre, Montreal, built in 1922 at a cost of $400,000 is now being operated. In addition to pump castings a full line of grey iron, bronze and gun metal castings is being produced.

Toronto.—The British-American Oil Company is enlarging its Toronto refinery by adding a new process building which contains the latest machinery for the production of certain lubricating oils. This plant will enable it to manufacture oils at present in demand which heretofore it has not made in large quantities. The company has also established six new branches in Ontario and Quebec, each of which has large tank storage accommodation as well as warehouse and office facilities.

M. S. U. A. ANNUAL REPORT

We always expect to find something interesting and original in the annual report of Mr. Stromeyer, Chief Engineer to the above association, and the present report has proved to be no exception. The fatigue tests are very unique and give us food for much thought. The "Principles of Boiler Design" treat with this old subject in a very comprehensive way and the specific heat formula, evolved after a large number of trials, is further interesting material on a very important subject.

Plans by the T. Eaton Co., Toronto, propose the immediate conversion of the older portion of their store, built in 1883, three storeys high with a frontage of 120 feet on Yonge st., into a modern structure of eight storeys. It will contain 200,000 square feet of floor space, equipped with traction elevators and other equipment of the latest type. The work of alterations will proceed without interfering with the regular business.

INGLIS PLANT TO MAKE CONVEYING EQUIPMENT

CHICAGO.—Webster Mfg. Co., manufacturers of elevating, conveying and coal rehandling machinery, have entered into an agreement with the John Inglis Co., Toronto, Canada, whereby the latter will make certain of the Webster lines in Canada. It is understood that a Canadian sales company has been formed with William Inglis, head of the John Inglis Co., and the president and vice-president of the Webster Mfg. Co., as chief owners. Mr. Inglis will be president of the new sales company, and it is announced that R. L. Smallwood, formerly general sales manager for the Dodge Mfg. Co. of Canada, will be sales manager. This organization will in no way affect the identity of the John Inglis Co., but will have to do solely with the marketing of Webster equipment as produced in the Inglis plant.

The Webster Mfg. Co. have factories here and at Tiffin, Ohio.

NEW PUBLICATION

We have received a very interesting booklet from De Lavel Steam Turbine Co., Trenton, describing the installation of a geared turbine, driving a direct current 600 K. W. generator and 500 K. W. alternator in the plant of the Crown Williamette Paper Co., West Lain, Oregon. The interest of this installation is that the turbo-generator provides sectionalized speed control, also that the various sections of the paper machine are driven electrically by D. C. motors. The relative speeds of the several rolls, as required to take up the "draw" or stretch of the paper being maintained accurately by synchronous motors belted to the direct current motor shafts with adjustable cone pulleys.

NEW EQUIPMENT IN CHATEAU FRONTENAC

(Continued from page 33)

ventilators. Also wine room refrigerator, installed by the Canadian Jewett Company of Bridgeburg, Ont.

The refrigerating system comprises a ten-compartment general storage refrigerator with two vestibules, also wine room refrigerator installed by Canadian Jewett Co., of Bridgeburg, Ont.

Smiths Falls.—Northern Buttons, Limited, is a new industry which located here at the beginning of the new year. At present, twenty-six hands are employed and this is likely to be increased to fifty by Feb. 1st. Manufacturers' Chemical Co. have purchased a site here and when in operation will employ between fifty and one hundred hands. Frost & Wood, manufacturers of farm implements, are doing a very good business for this season of the year, and are employing four hundred hands. Wood Sawmills, owned and operated by the United Farmers, had a ten-thousand dollar loss by fire recently. Valuable woodworking machinery was destroyed. They intend to rebuild and equip a new plant immediately.

FOR SALE

SALESMAN WANTED FOR STEAM SPECIALties, power house and heating equipment. State age, education received ,and previous experience if any. Box 101, Power House.

BURNHAM STEAM PRESSURE PUMP, 10 IN. x 1⅛-inch. x 12 in., nearly new, with Fisher governor attached. W. Ahearn, 538 McLaren St., Ottawa. When answering this advertisement please mention this paper. P.F.H.

I. H.C. 12 H.P. GAS ENGINE FOR SALE—ALL in good running shape, with 33-inch clutch pulley; will be sold reasonable on easy terms. Apply W. Harrison, & Son, R. R. 5, Guelph. When answering this advertisement, please mention this paper. P.F.H.

ABSOLUTE BELTING BARGAINS—BELTING every description; rubber hose, thresher supplies, tank pumps, pump leather feeds, canvas, McGill auto powers, special reduced prices; for quality and price, you can't beat us. N. Smith, 134 Adelaide west, corner of York, Toronto. When answering this advertisement, please mention this paper. P.F.H.

TAYLOR SAFES FOR SALE—RARE OPPORtunity to secure a safe at small cost. They are in splendid condition. Inside dimensions and prices are as follows: 15" deep, 2 ft. 6" wide, 3 ft. 11½" high, fitted with built-in compartment. Price $250.00. 18" deep, 2 ft. 8" wide, 4 ft. 5" high, fitted with steel compartment. Price $200.00. Apply Box 10, POWER HOUSE.

FOR SALE
Fuel Oil Storage Tank
10,000 GALS. CAPACITY.

This is a new tank. We have not yet taken delivery of it, and offer it at a very attractive price.

MR. VOGAN, The MacLean Publishing Co.,Ltd, 143 University Ave., TORONTO.

Man Either Progressive or on the Retrograde

By **G. M. EATON**

LET Y equal the burden of responsibility imposed by the job.

Let X equal the number of men competent to shoulder the load.

Analyzing the limits, we find when no burden of responsibility exists, anybody can fill the bill, and therefore when Y = zero, X = infinity.

When the burden is infinite, no man can stand the gaff, and therefore when Y = infinity, X = zero.

Analyzing the approaches to the limits, we see that a small increment of responsibility above zero eliminates a very great number of individuals. Each successive increment, however, eliminates a decreasing number.

We can, therefore, at once describe the general shape of the curve as referred to rectilinear co-ordinates. It is asymptotic to both axes and is concave up. It is obviously approximated by the hyperbola with the equation XY = a constant. See Fig. 1.

For purposes of discussion, we will neglect the possible detail discrepancies between this equation and the actual and proceed as if it were fundamentally true. true.

Stated in words:

The product of responsibility and the number of men competent to bear it, is a constant.

Life in the abstract is a hyperbola.

Life in the living is climbing the hyperbola.

We will first study a few of the phenomena encountered in ascending a single hyperbola, bringing out later that a third dimension is involved and that no real life exists in "Flatland."

Consider the case of a group of university graduates entering an industrial establishment as students. In the first analysis the curve covered the entire human race, but with Mr. Einstein's permission, we will change our measuring stick and the curve will at once represent the ability the employer expects to find in these men. They start at the right-hand end of the curve, but obviously their load-sustaining capacity covers a wide range. There is, therefore, an apparent discrepancy in our equation.

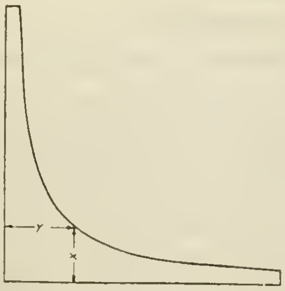

Fig 1

There was a time when it was considered up to the young man—and up to him alone—to show what stuff was in him. To-day the existence of a joint responsibilty is recognized. The mist must be penetrated by both the man and the establishment. The more thorough and effective the effort on both sides, the quicker will be the clearing of the atmosphere, and one head after another will appear above the fog, to start moving toward its logical position on the curve, till the group is strung out and each man moving at the speed dictated by his ability and effort. We will assume that even the least able man has made material advance.

Now take that part of the curve intercepted between the men of the highest and the lowest ability; again apply the principle of relativity, and Fig. 1, after a fashion, represents the group from a somewhat different angle. The lowest man has advanced in his actual capability to serve, but relatively he has slipped back. We have, therefore, a new slant on the adage that "A man goes up or down and cannot stand still."

Periods of depression like the one we have just experienced, drive home the lesson that the opportunity to serve goes hand in hand in the long run with relative ability to serve.

We can often learn much from analyzing the slope of a curve. The going at the right-hand end looks easy, with small chance to slipping. But every step up demands sticking to it harder to develop the requisite adhesion, and shortly, digging-in is essential to secure sound toe-holds, each successive hold requiring increased effort.

We have been analyzing what we believed to be a single plain curve, but we find on close scrutiny that we are dealing with a laminated structure, and incipient cleavage planes are found to exist. See Fig. 2. The hyperbola exists in each lamination, and the various men are beginning to segregate as directed by their several abilities and preferences. Some gravitate to salesmanship; some to engineering; etc.

After a little more time has elapsed, and as we look with a stronger glass, we find further latent cleavage as specialized leanings become defined.

Thus, we find the industrial life to be a hyperbolic prism with a detail structure built up of many laminations akin to a mica crystal. We have spoken of cleavage, and our analogy to mica may profitably be pushed a bit further. Each lamination is complete in itself, but the whole crystal is strong only as each lamination remains sound and in a state of close cohesion with its co-operating laminations. And as the lamination is to the crystal so the department is to the establishment, the establishment to the industry, and the industry to the college, and both to life in all its phases, nations and races.

The lamination that "sluffs" off its close relation to the whole ultimately disintegrates and vanishes, leaving perhaps a gap for a while, which is healed with the lapse of time, and life goes on, and jobs go on, and men go on.

The life prism has smooth perpendicular sides. The graduate student lamination stands at a dizzy height, measured with the yard-stick of the boy who cannot afford the luxury of a university training and in a lesser degree to him who earns his way through. The college man who early recognizes his course as a ladder that will reach to this level is fortunate, while often the man who has had to work his way finds that the very operation has served to sharpen the calks on his boots, so that they grip firmly on the steeper pitches of his chosen hyperbola.

Each individual—and we here revert to our original scale and include the human race—has his own ideal structure of life. If he has been free to follow his natural bent, he sees his particular lamination at the top of the prism, and from this height he looks down with more or less toleration on what, to him are more lowly callings. If his conception pictures more glorified planes, and he has any red blood in his veins, he will move heaven and earth to bore up his ideal, and start to climb the new heights from which with broader vision he can see, and aspire to still nobler achievement.

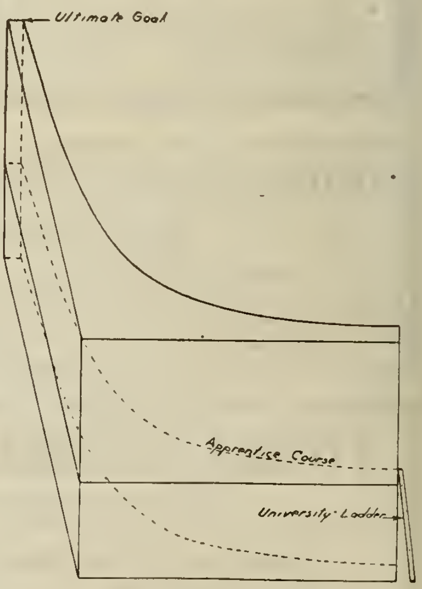

Fig 2.

DARLING BROTHERS EQUIPMENT

Installed in the

Mount Royal Hotel, Montreal

This hotel is heated by Webster System throughout, manufactured by Darling Brothers. All hot water used in the building is furnished by five Darling Heaters.

Below is shown the two automatically controlled Darling Vacuum Pumps installed in the Mount Royal Hotel.

The choice of this equipment for "the largest hotel in the British Empire" is evidence of the popularity of the lines manufactured by Darling Brothers—a popularity due to long and satisfactory service.

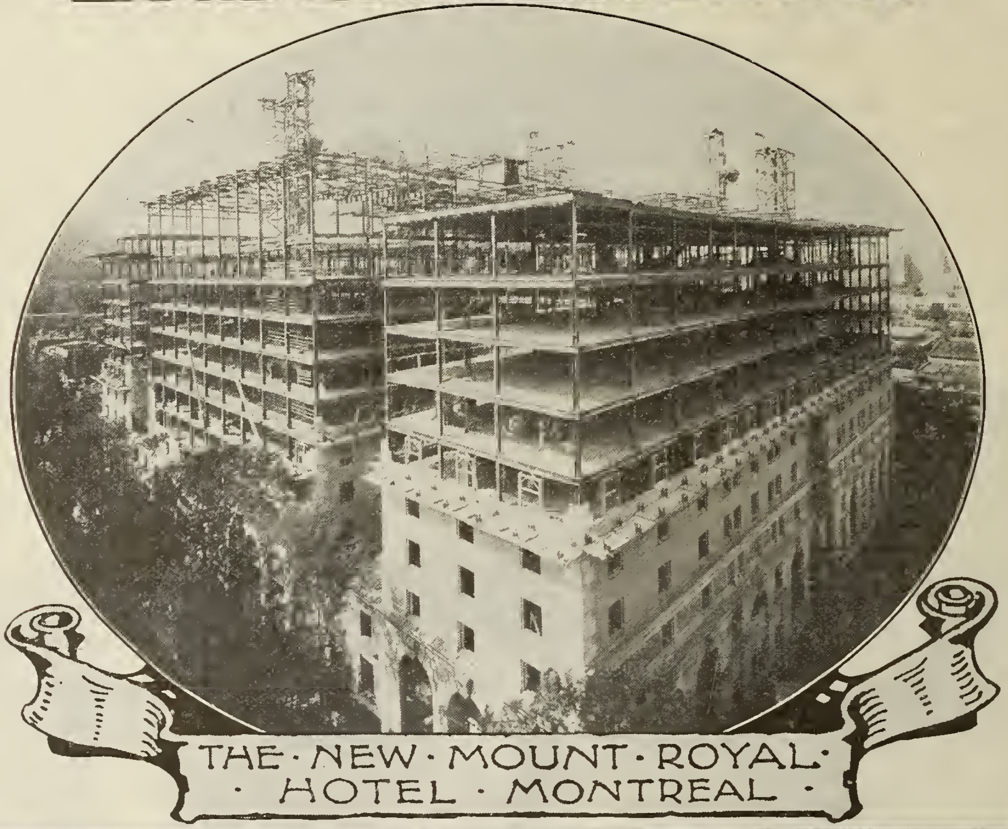
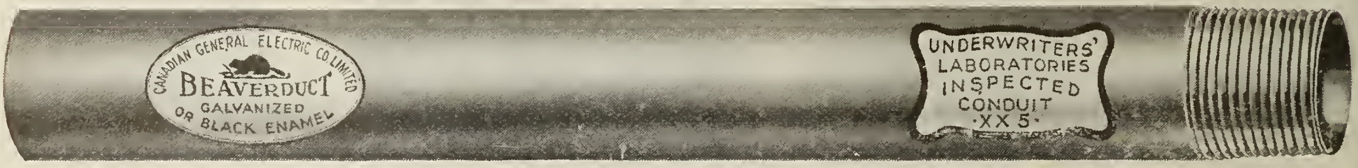
ANOTHER BEAVERDUCT INSTALLATION



THE · NEW · MOUNT · ROYAL ·
· HOTEL · MONTREAL ·



CANADIAN GENERAL ELECTRIC CO LIMITED
BEAVERDUCT
GALVANIZED
OR BLACK ENAMEL
UNDERWRITERS' LABORATORIES INSPECTED CONDUIT ·XX 5·

Beaverduct is a Canadian made conduit, manufactured in a modern plant under the underwriters' inspection. Its use on such an installation, as this, is a fitting testimonial of its superiority.

Good conduit can only be produced in a plant where the equipment permits only absolutely clean material being used. Electrical apparatus and plating solutions must be kept up to the mark under scientific management. The proper application of the enamel, after the galvanizing of the outside, is of vital importance. And, lastly, rigid inspection.

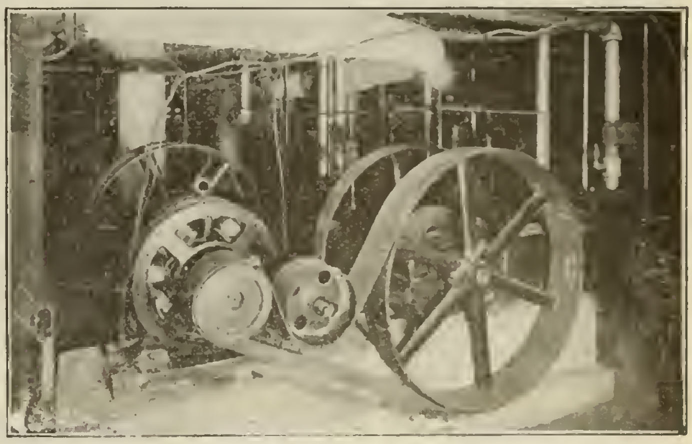
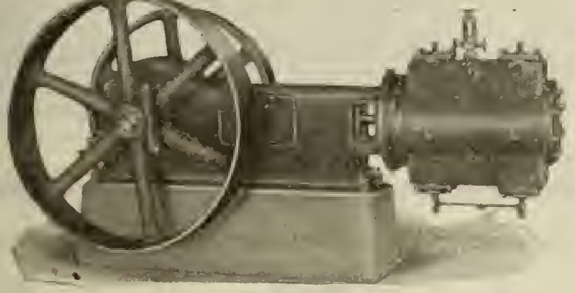
Ingersoll-Rand *Compressors* *Serve* Mount Royal Hotel

Pure, aerated water for the largest and most modernly equipped hotel in the British Empire is supplied by an "Ingersoll-Rand" Imperial Type "VA" Air Lift System.



The Compressor Installation Under Construction.

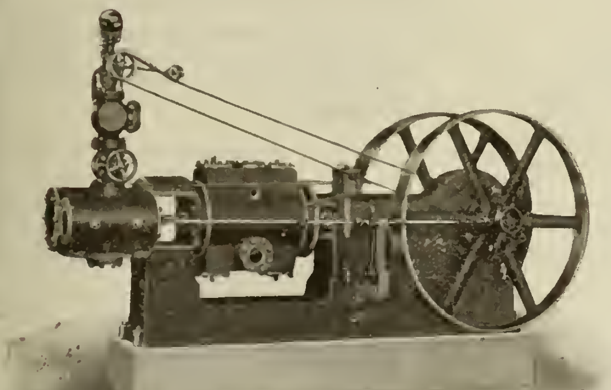


A Class "E-R-1" Power Driven Compressor is used for regular service at the Mount Royal Hotel.

There is no better source of water supply than a properly designed Air Lift System. The water secured is cool and of the best quality; the supply steady and reliable, and the cost of pumping is usually lower than by any other means.

Satisfactory performance, however, is largely dependent upon the experience of the manufacturer and the efficiency of the equipment used.

This Company's experience in Air Lift Pumping is coincident with the inception of this method of elevating well water and its reputation for the production of highly efficient air compressors—*the heart of an Air Lift System*—is unchallenged.



For Stand-by Purposes the Mount Royal Hotel employs a class "FR-1" Steam Driven Compressor.

In the New Mount Royal Hotel

IT MIGHT be taken as singular tribute that Foxboro indicating and recording instruments were installed in the largest hotel in the British Empire, "The Mount Royal" of Montreal. But as a matter of fact Foxboro instruments are used in the largest establishments throughout the country.

The view here shows a special instrument-board in the chief engineer's room of the Mount Royal. All the instruments on the board were made by the Foxboro Co., of Foxboro, Mass., and were supplied by Peacock Brothers, Ltd., Montreal.

The indicating instruments are mostly used for indicating water pressure; while the recording instruments are for showing boiler pressure, outside temperature, flow and distribution.

We shall be glad to furnish complete information regarding Foxboro instruments. Write to Dept. C.F.

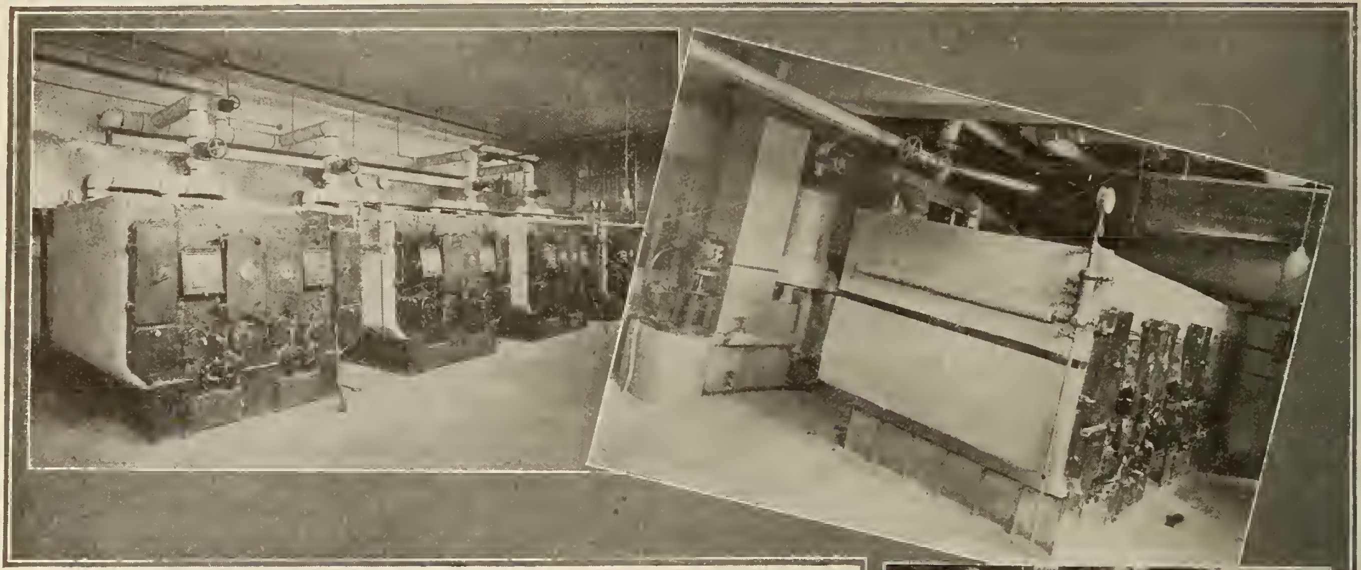
A Spencer for Every Heating Requirement

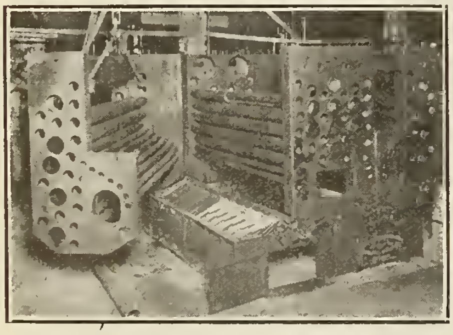
Hot Water or Steam

SPENCERIZED HEATING
SAVES FUEL SAVES LABOUR



Note these Boiler Rooms
Compact, Smokeless, Clean and Efficient.

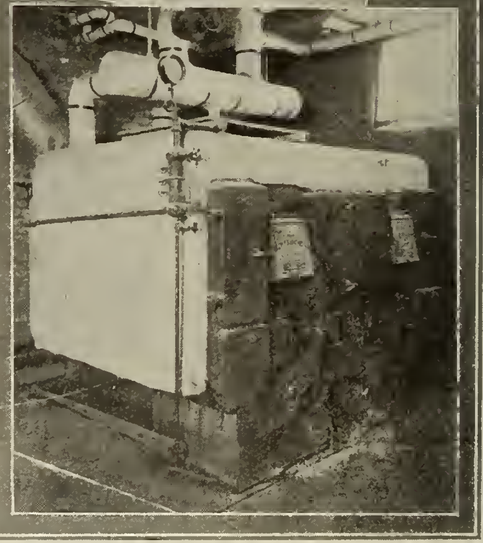
Installations of every size from the smallest to the largest of Public Buildings.



Sectional view of the Spencer, the Master Mind of Boiler Construction

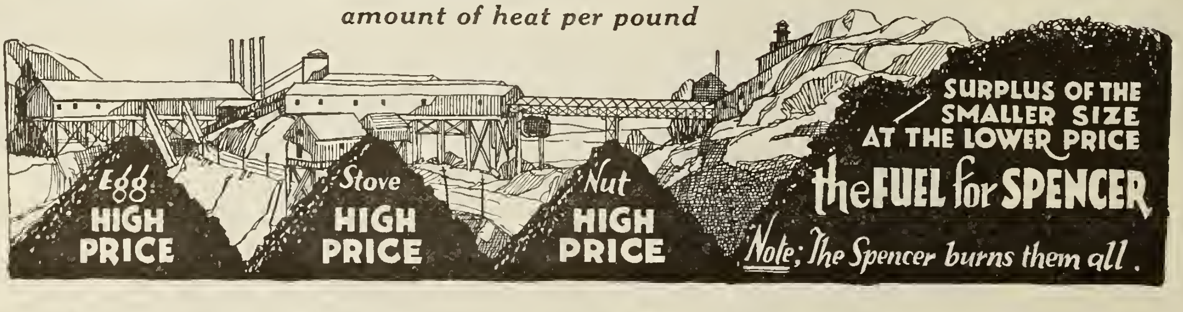
For
OIL BURNING

No radical change necessary to make it the most suitable and satisfactory for Oil Burning.



WRITE FOR INFORMATION

All sizes of Coal contain the same amount of heat per pound



Egg HIGH PRICE
Stove HIGH PRICE
Nut HIGH PRICE
SURPLUS OF THE SMALLER SIZE AT THE LOWER PRICE
the FUEL for SPENCER
Note; The Spencer burns them all.

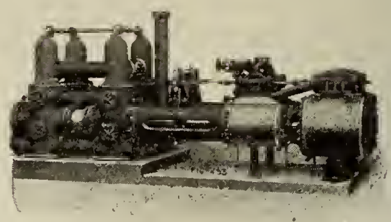
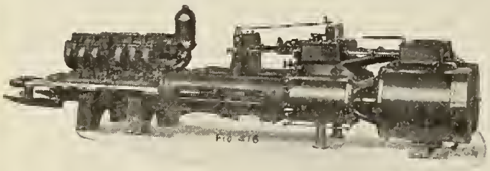
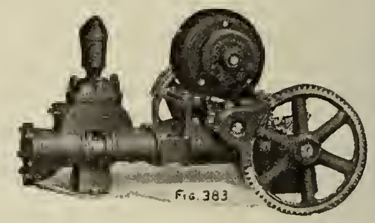
McGOWAN PUMPS

STEAM DRIVEN -:- POWER DRIVEN

Every Part Interchangeable







Reduce Complaints

The consumer whose service is interrupted "Can Hear No Excuse." Reduce complaints by using McGowan Duplex Steam or Power Pumps to handle your water system.

Every detail of our designs has been given the closest attention and the result of our 70 years in business brought to bear on same.

All parts of McGowan Pumps are interchangeable.

All parts are made to gauge.

MAGNOLIA

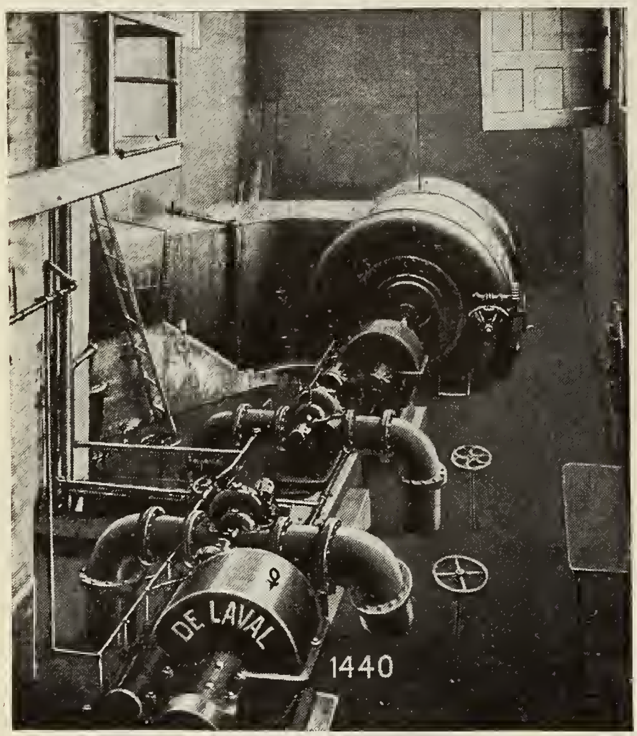
Magnolia Anti-Friction Metal has been proven by U. S. Government tests to improve bearing service, effect saving in metal, power, fuel, lubricants, machinery parts and maintenance attention, and to be decidedly superior for its work. It is easy to handle, is absolutely homogeneous, and comes in convenient forms, for ready use. It will pay you to standardize on Magnolia Anti-Friction Metal. Its users invariably prefer it to lower grades.

Magnolia Metal Company, 113 Bank Street, New York

Chicago San Francisco Montreal

REG. U.S. PAT. OFF.

ANTI-FRICTION METAL



Water Pumped by Water Power

THE City of Cornwall, Ont., was formerly supplied by triplex and duplex pumps driven by a horizontal hydraulic turbine, with steam driven pumps for emergency service. Having plenty of water available under low head, the City installed two De Laval centrifugal pumps driven by low speed water turbines. Each pump can handle the normal pumping load with a capacity of 3,500,000 gallons per day against a service head of 180 ft. and operates at a normal speed of 1,670 R.P.M. To obtain the inherent high efficiency of the De Laval centrifugal pump, the pumps are driven through De Laval double helical speed increasing gears by water turbines operating at their normal speed of 200 R.P.M., with a loss in transmission of power from turbine shaft to pump shaft of less than 1½%. Through a simple piping arrangement, the two pumps can be operated in series at a moment's notice to deliver over 4,500,000 gallons per day against a head of 308 ft. for fire protection.

Read our book W-100 "Ten Years' Progress in Water Works Pumps."

A Striking Message

A STRIKING message to manufacturers of power-house equipment is derived from a letter written by a "Power House" reader in reply to a request for a criticism of the paper and for suggestions as to how it could be improved. Here is the letter:

"I believe Power House compares favorably with other power-house journals in many respects. One department I would like to see at least three times its present size is the selling section. Many of the ads. are from all-American U.S. firms but there must be many others, some of them with Canadian branches and agencies, who do not carry an advertisement in Power House. This is a **mistake on their part**, but for all I know to the contrary it may be due to the lack of energy on the part of the Power House ad. manager in getting after them. **It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages so much as on the ADVERTISEMENT PAGES."**

Why PYRRICO JOINTLESS FURNACE LINING

is better than fire brick—

This plastic furnace lining is better than fire brick because:

1. It is jointless.
2. It is plastic.
3. It is air and gas tight.
4. It will stand 3100° F.
5. It will save fuel.
6. It can be installed by inexperienced labor.
7. It will outlast fire brick.
8. It can be used in any boiler, furnace or oven.
9. It can be used where ever fire brick is used.
10. It cannot be excelled for patching broken and burned out linings.

JOINTLESS FIRE BRICK CO.

1142 Clay St., Chicago, Ill.

DISTRIBUTORS: Beveridge Supply Co., Ltd., Montreal; Shell Bar Boico Supply Co., Ltd., Toronto; Evans, Coleman and Evans, Vancouver, B.C.; Winnipeg Supply and Fuel Co., Winnipeg; Gorman's, Ltd., Calgary, Alta.

Even if you put

A water tender on every boiler—

—every man working his best to feed only one boiler — even then you could not get the safety, and the fuel savings, that are assured by the COPES SYSTEM OF BOILER FEED REGULATION.

Careful tests between COPES feed and hand feed, in actual practice—have proved again and again that the fuel savings and labor savings of the COPES pay back its cost many times over.

The COPES varies the feed water instantly, according to every change in load conditions.

It is simple and strong with no uncertain features of construction no springs or diaphragms, no floats or displacement bodies. The only parts are a sturdy expansion tube and a balanced valve. There is no chance for sticking or lag.

Its reliability has made the COPES the standard it is used by 98 per cent. of the leading Central Stations.

Our new booklet "Regulating Boiler Feed Water" shows how marked savings in fuel—2% to 8% ordinarily—can be effected by COPES Regulation.

MONCRIEFF'S "UNIFIC" WATER GAUGE GLASSES

Moncrieff's "Unific" is not a cheap glass. But because it outlasts many ordinary glasses the "Unific" is economical. British Made.

The "Unific" does not readily corrode. It resists extreme changes of temperature and withstands the highest working steam pressure.

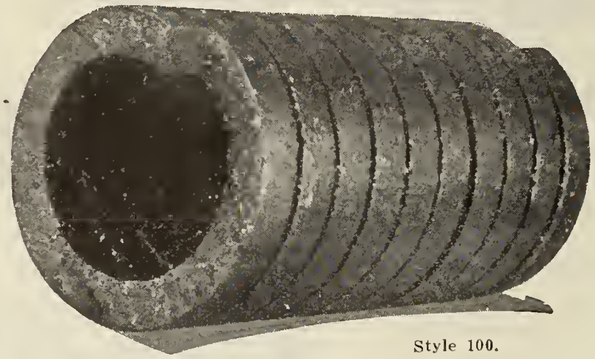
A COMPLETE SERVICE IN
"John Crane"
FLEXIBLE METALLIC PACKING



Style 100.

You have not demonstrated Metallic Packing until you have used "John Crane."

Style 100 above is the key to our complete packing service. It is spirally wound babbitt foil impregnated with purest graphite. Has low coefficient of friction; is non-abrasive, practically impervious to chemical disintegration and made in most convenient possible form.

INVESTIGATE. Let us send you our 64 page scientific text book "Metallic Packing." Of vital interest to every engineer. Complimentary. Write today.

Tycos and Condensers

Efficient condenser operation is only determined when accurate records of ingoing and outgoing temperatures are kept and studied. This is possible with a *Tycos* Bi-Record Recording Thermometer. It writes both ingoing and outgoing temperatures on the same chart.

Power operators send for catalog part one. A reference book on temperature instruments for power plants.

A TYPE FOR EVERY PURPOSE

And Service 'way beyond the average!

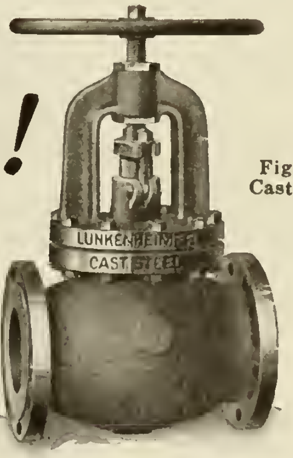

Fig. 606
Cast Steel

Be it a small or large size for low or high pressures and temperatures, there is a Lunkenheimer Valve especially suited to the purpose. Every type is designed to give maximum service under extreme operating conditions, and with the line complete, standardization throughout the plant, with its many advantages, is easily accomplished.

With seating surfaces regrindable and all parts made to gauge and renewable, the installation of Lunkenheimer Valves means permanence in the line with a minimum expense for maintenance and repairs.

Our catalog No. 58-D.C. illustrates and describes the various types in detail. A copy will be sent on request.

If you have a valve problem, we will help you,—no obligation.

Gouin Dam Under Construction

CANADA CEMENT
CONCRETE
FOR PERMANENCE

The Canada Cement Company maintains a comprehensive library of information. This library and the Service Department are at the disposal of all interested in concrete constructions.

The Gouin Dam
on the
St. Maurice River

THE Province of Quebec has adopted the policy of regulating the flow of its rivers. This policy was first put into effect on the St. Maurice River, with the construction of the Gouin Dam, forming the second largest artificial reservoir in the world.

The dam is located 240 miles from the St. Lawrence and completely controls the water supplied by a drainage area of 3,650 square miles.

Seventy-two thousand yards of concrete were used in it. The concrete was mixed in proportions of 1:2:5, into which was embedded an average of a little over 15 per cent. of displacers or "plums."

This regulation work is responsible for a tremendous power increase — the amount of power now generated on the St. Maurice River being 500,000 H. P., with an equal additional amount possible.

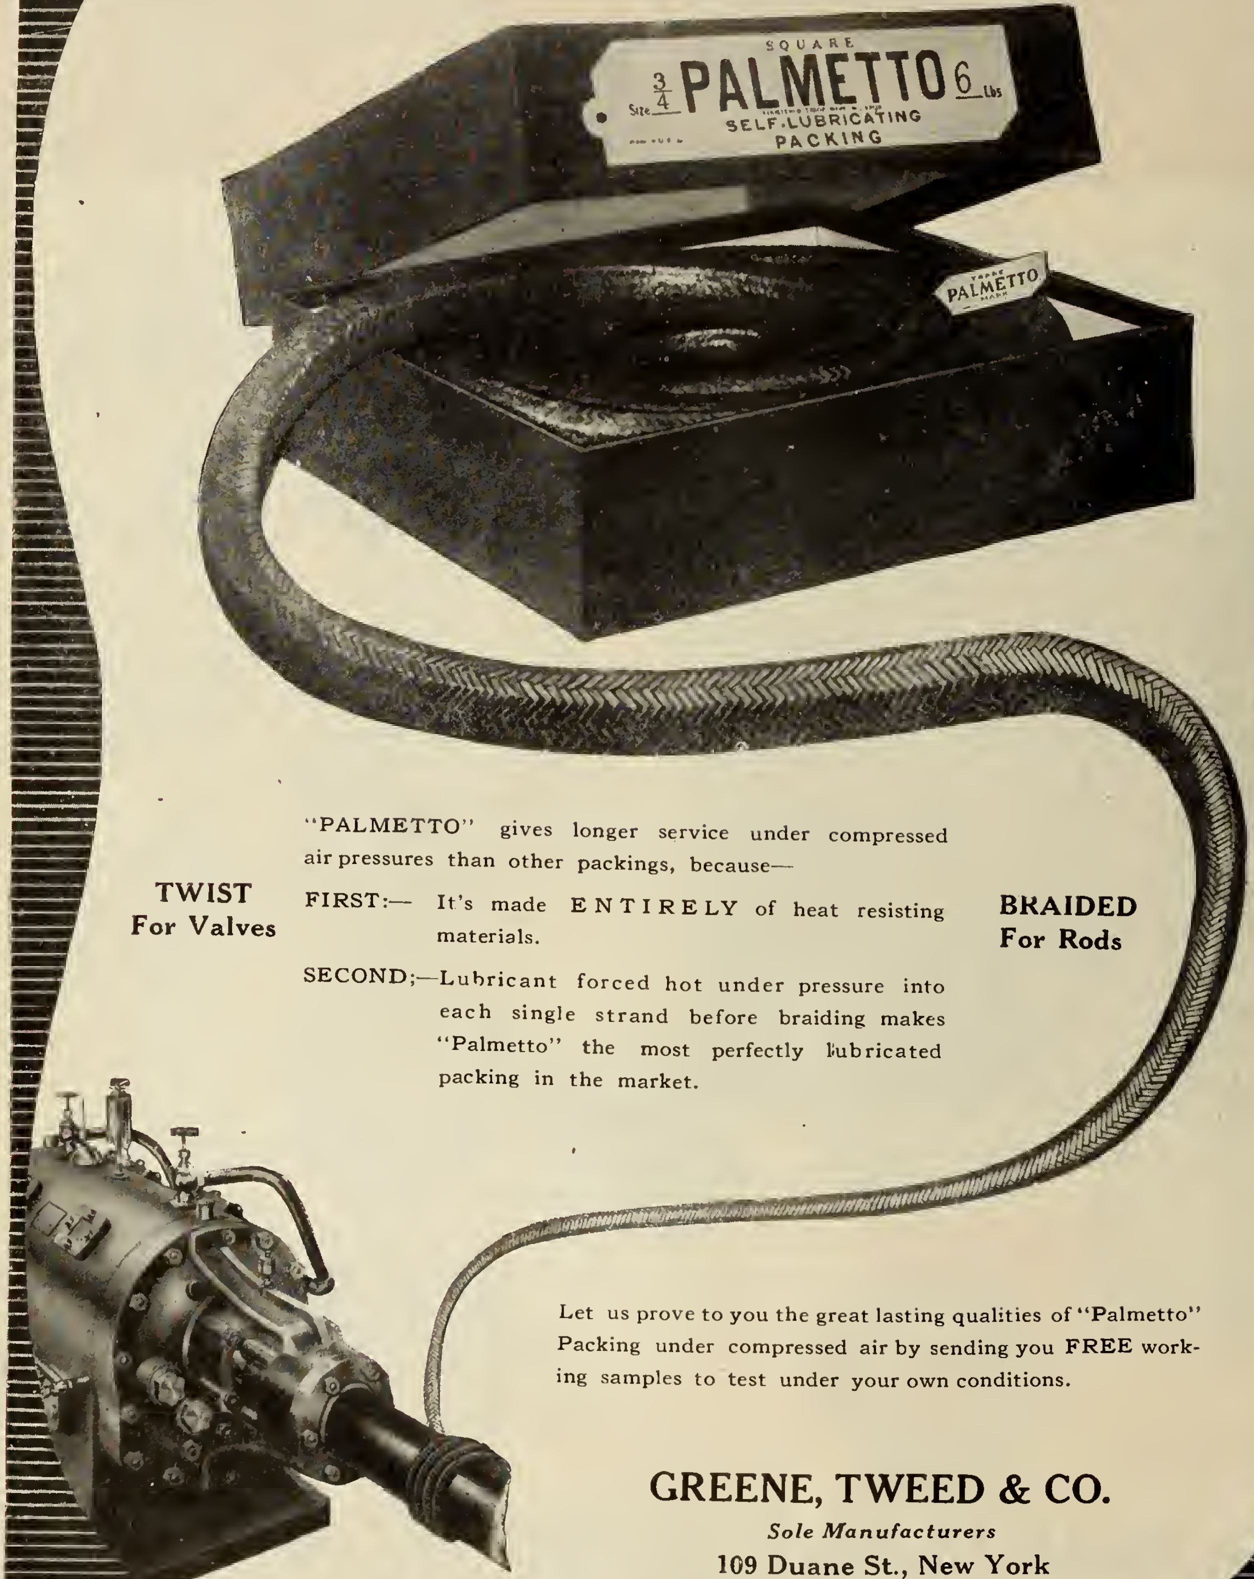
How Long Does Your Rod Packing Last Under Compressed Air Pressures?



TWIST
For Valves

"PALMETTO" gives longer service under compressed air pressures than other packings, because—

FIRST:— It's made ENTIRELY of heat resisting materials.

SECOND;—Lubricant forced hot under pressure into each single strand before braiding makes "Palmetto" the most perfectly lubricated packing in the market.

BRAIDED
For Rods

Let us prove to you the great lasting qualities of "Palmetto" Packing under compressed air by sending you FREE working samples to test under your own conditions.

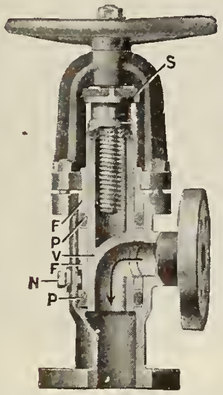
These YARWAY SEATLESS BLOW-OFF VALVES

have been in Continuous Service Since 1910



Yarway Seatless Blow-Off Valve—send for celluloid model illustrating operation of this unique valve.

In June, 1910, the Stanley Works installed three YARWAY SEATLESS BLOW-OFF VALVES in their New Britain, Conn., plant. To-day, after more than twelve years of continuous service, these valves are still in good condition.

In March, 1911, the same company installed three additional YARWAY SEATLESS BLOW-OFF VALVES; in May, 1912, three more; in September, 1912, three more; in December, 1920, two more—a total of four repeat orders.

All of these valves are giving excellent service.

The Stanley Works is one of several hundred concerns that have made a permanent investment in YARWAY SEATLESS BLOW-OFF VALVES. Names and records of other users are given in Booklet B-410. There's a free copy here for you—write for it to-day.

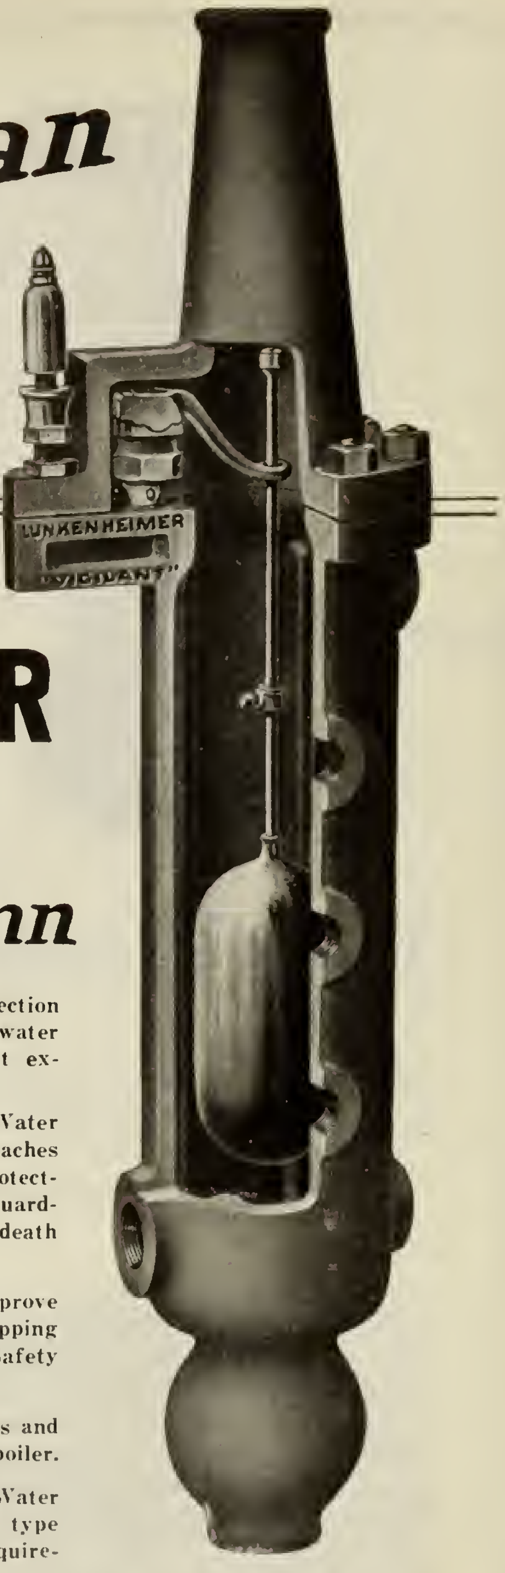
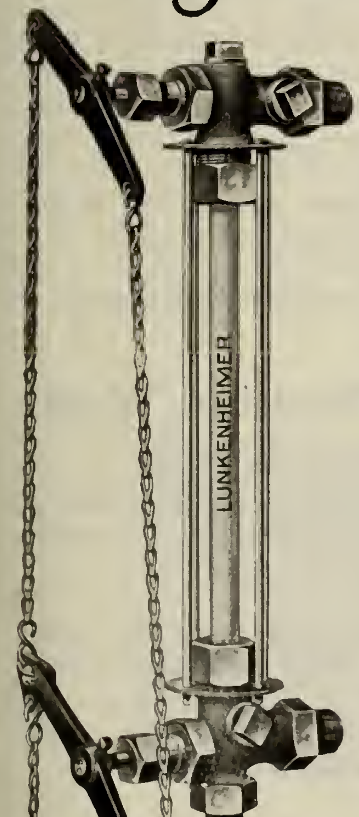
Sounds an alarm

—when danger is near.



LUNKENHEIMER

"Vigilant" Safety Water Column



A safety device as essential for the protection of the boiler against extreme high or low water levels as the Pop Safety Valve is against excessive steam pressure.

The Lunkenheimer "Vigilant" Safety Water Column sounds an alarm before the water reaches either danger limit. It thereby aids in protecting the boiler against accident and in safeguarding the boiler attendants against injury or death and the plant from destruction.

Statistics covering boiler accidents will prove the desirability — yes, necessity of equipping boilers with the Lunkenheimer "Vigilant" Safety Water Column.

For the highest prevailing steam pressures and in sizes suitable for any make or type of boiler.

From the large variety of Lunkenheimer Water Gauges and Gauge Cocks may be selected a type particularly adapted to meet individual requirements.

Ask for Booklet 519-DC.

Bailey Boiler Meter. Records steam flow, air flow and flue gas temperature all on one chart.

BAILEY
Boiler Meters

It is not enough simply to know how much steam a boiler is making for it is equally important to know how efficiently this steam is being generated. A boiler may make a good deal of steam but do it very inefficiently as when it is running at low rating during the light-load period.

Manufacturing conditions to-day make it imperative to

Prevent Needless Waste

And in a boiler plant the best results can be obtained only by a constant record of the relationship between the operating factors.

This is the main purpose of the Bailey Boiler Meter. It shows the fireman exactly what the operating conditions are at every instant so that he can control steam output and maintain maximum efficiency.

Write for Bulletin No. 42

Bailey Meter Company, Limited
177 Delorimier Ave. Montreal, Que.

All it costs is $136.22 per annum

to own this modern, new, thoroughly efficient Boiler. Think of it! Think of the coal savings, the repairs savings, the boiler room labor savings you can effect if you discard that present worn out, inefficient Boiler and put in a high-grade, up-to-date Boiler from us. And the cost is really moderate. The sum mentioned above is an annual 7% interest charge on a Boiler investment of $1,946, which gets you a 66″ x 16′ horizontal return tubular Boiler, 110 h.p., 125 lb. pressure, built to suit Interprovincial Codes, complete with suspension harness and columns. Other sizes in proportion. Easily one of the best investments you can make because your savings will offset several times this modest investment charge.

Instal National Hand Fired Stokers which give unusual steam results from low grade fuels, with common, inexpert labor, and your savings will be very substantially increased.

Write us for further particulars.

SINCE 1864

Service Considered—

There's Only One Real Test

Whatever may be claimed for any belting, the one sure way of testing its real value is by watching your transmission cost sheets.

In many of the largest Canadian shops, the adoption of

D. K. McLAREN'S BELTING

is giving a "service on the pulley" that is reducing transmission costs to an absolute minimum. One reason for this is the

Genuine British Oak Tanning Process

to which every inch is subjected—that, and the fact that only the **back portions** of specially selected hides are used in its manufacture.

D. K. McLaren's Leather Belting is stamped with an Oak Leaf as your guarantee of this—look for it.

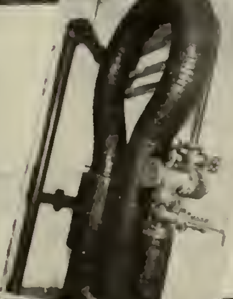
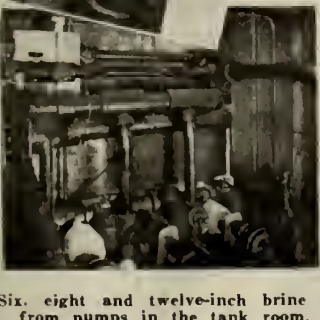
Part of 250 feet of double 15-inch brine main in the basement.



Eight-inch return expansion bend.



Six, eight and twelve-inch brine lines from pumps in the tank room.

SIZE Is No Obstacle

IN THE Harbor Commissioners Cold Storage Plant at Montreal, Canada, are long runs of 8-inch, 12-inch and 15-inch brine lines. All of them, with their immense fittings, bends and connections, are insulated with Nonpareil Cork Covering.

The selection of Nonpareil Cork Covering for such work as this was dictated by the necessity for using a covering that not only would afford the utmost insulating value, but that could be depended upon absolutely for permanence. Think of the expense of replacing insulation on such lines. No possible saving (?) in the first cost of some inferior material could justify such a risk.

Whether you have long runs of big lines or short runs of little ones, Nonpareil Cork Covering offers you the same assurance of permanence and maximum saving of refrigeration. No plant, whether large or small, can afford to insulate brine and ammonia lines with anything less efficient and durable than Nonpareil Cork Covering.

Write for data on cold lines losses and how to stop them. Samples and full information will be furnished promptly and free of charge.

"For Reliable Service give me YORK Equipment"

When the Operating Engineer of an Ice Making or Refrigerating Plant insists upon the Plant Manager buying York Ammonia Fittings and Supplies, he knows he is saving himself a lot of time and trouble and also reducing the operating costs of the plant.

He knows, because he has learned through past experiences of his own, or perhaps from another Engineer, that York Equipment is designed and made to meet the severest Service.

Surely, the man who is responsible for the operation of the plant, who sees and handles the equipment every day, should be best able to judge the merits of each piece of apparatus.

And the engineer out of justice to his employers and to himself, will recommend York Apparatus, which he realizes will give satisfactory results in actual service. That's why more York Ammonia Fittings and Supplies are sold each year than any other make.

There is perhaps no other concern of its kind in the world able to handle such a large number of orders or such a heavy volume of business.

A trial order will convince you of the Superior Quality of York Ammonia Fittings and Supplies.

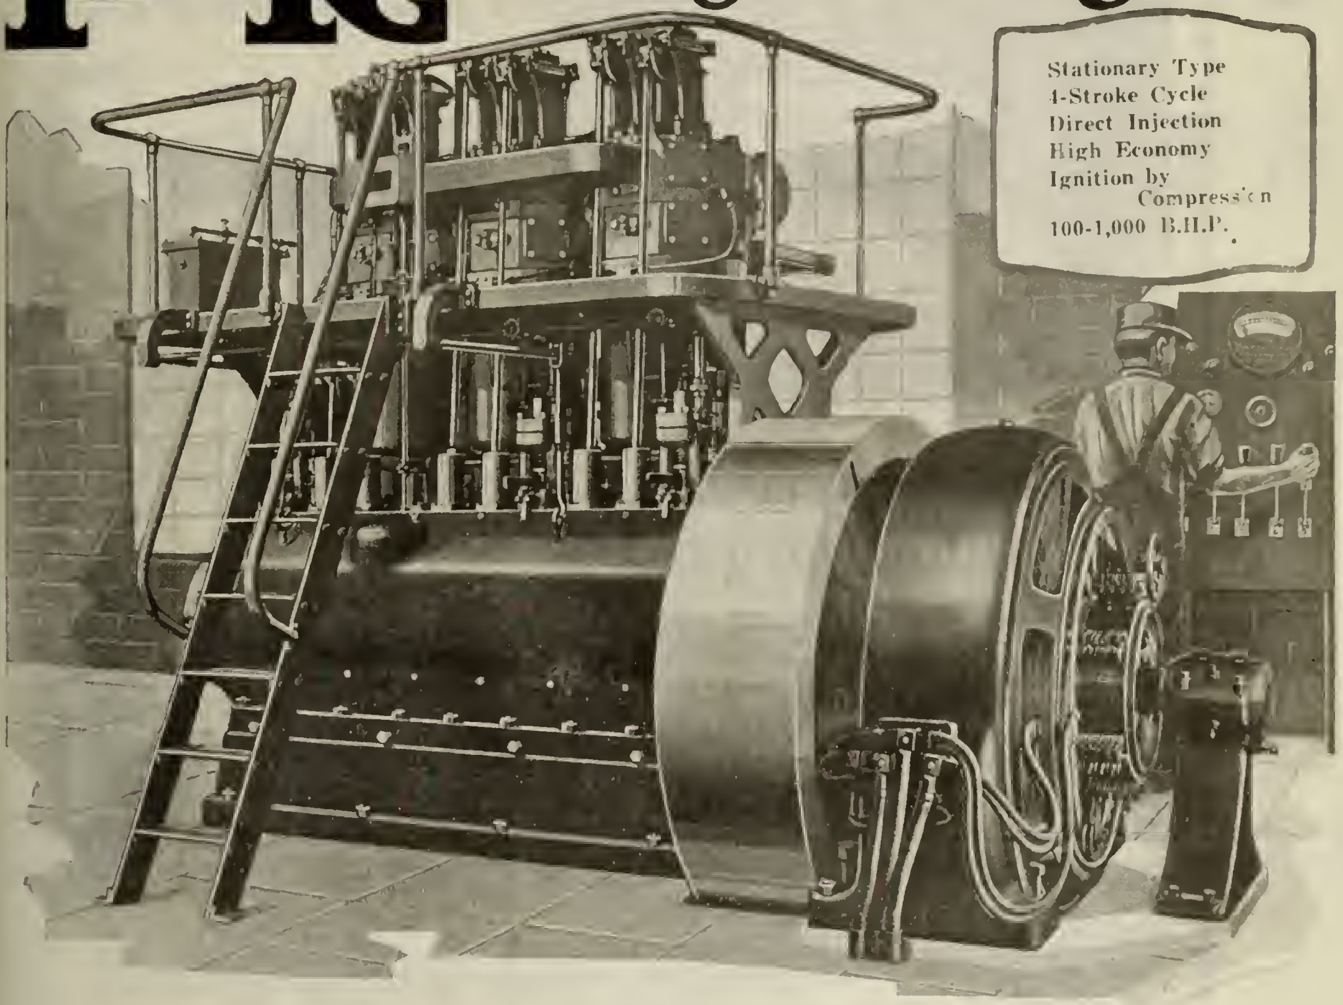
P-R Heavy-oil Engines



Stationary Type
4-Stroke Cycle
Direct Injection
High Economy
Ignition by
Compression
100-1,000 B.H.P.

Lowest Cost Per Horse Power Hour

There is but one true measure of efficiency of the complete power plant and that is the **cost per unit of useable power.**

The P-R Engine converts the fuel **directly** into power; no boiler plant is used. This alone represents a large saving.

Furthermore, the P-R Engine operates with remarkably high efficiency, the **guaranteed fuel oil economy at full and ¾ loads being 0.45 pounds per horsepower hour and the guaranteed lubricating oil economy one gallon per 4000 horsepower hours.**

Fuel injection is direct and positive without the use of compressed air.

Ignition is by temperature of compression alone, there are no hot plates or bulbs or liners.

The P-R Engine is not only mechanically efficient, but has many remarkable features which make it easy to take care of.

The P-R Engine produces each unit of **useful work at lowest cost.**

Horizontal and marine types are also available.

Write for bulletins describing the type or types in which you are interested.

"Multiple retort" in everything but price—

BEFORE the *"lateral retort"* principle was developed there was no such thing as a strictly *underfed* side-cleaning stoker. Consequently, the many advantages of underfeeding coal were confined to more expensive stokers of the high-duty multiple retort type.

Now, as a result of the revolutionary *"lateral retort"* principle, the advantages of the multiple retort stoker —high capacity and efficiency—are combined with the advantages of the side-cleaning stoker—lower first cost, reduced installation cost, and adaptability to old boilers.

The *"Lateral Retort"* Stoker is not claimed to be a substitute for multiple retort stokers—*but*—it *does* bring the advantages of multiple retort stoking to the plant that otherwise would install an inferior stoker, thus providing multiple retort efficiency while effecting a marked saving in initial and installation cost.

The illustration above shows how the truly underfeed effect is accomplished. The coal follows the path of the arrows. It is first underfed along the line of the main arrow into the central retort by means of a main ram. It is then underfed—always underfed—into the *"lateral retorts"* by means of an auxiliary steam cylinder which operates lateral pusher rods.

There is only one simple moving unit for distributing fuel in five or more *"lateral retorts"* and, since this feeding mechanism is controlled independently of the main fuel feed, ideal distribution is possible under all conditions.

A trench 6 to 18 inches below the floor line is sufficient excavation for ash pits. This reduces installation cost and makes the stoker adaptable to boilers already in service. The many good points of this stoker are covered in greater detail by a new bulletin. Where shall we send it?

The "Lateral Retort"
Trade Mark
Stoker

Trade Mark

Advantages of
the *"Lateral Retort"*
Principle

Coal is underfed throughout—not overfed on to side grates. This is the only truly *underfed* side-cleaning stoker.

One simple moving unit for five or more retorts—The feeding mechanism of the *"loterol retorts"* is controlled independently of main feed, permitting ideal fuel distribution under all conditions.

Simplest cleaning mechonism—a perfectly balanced dump plate easily operated by hand.

No need for basement ash pits—A trench 6 to 18 inches below the floor line is sufficient excavation for ash pits. This greatly reduces installation cost and makes the stoker adaptable to boilers already in service.

Plate tuyeres — reduce siftings and lower replacement cost.

High air cooled front and rear tuyere blocks—keep fire and clinkers away from front wall and bridge wall, reducing furnace maintenance.

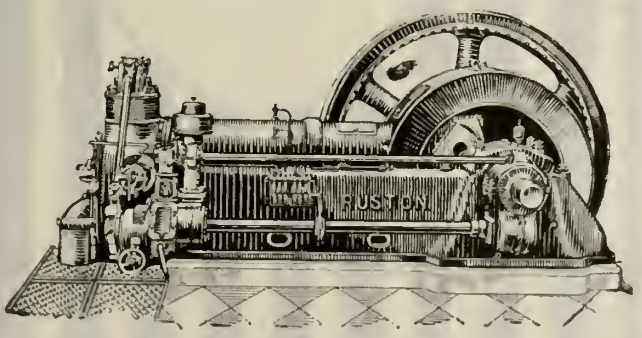
Automatic Valved Soot Blowers

Soot blowers having automatically operated valves were originated and developed by us, and are covered by patents issued and pending. Infringements of these patents will be prosecuted.

Diamond Specialty Limited, Windsor, Ont.

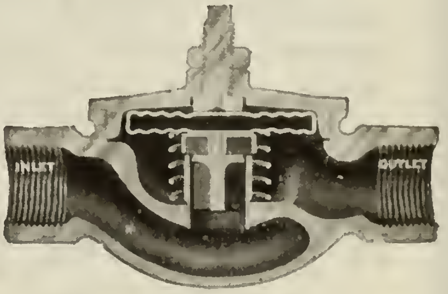
Ruston & Hornsby Ltd.

Lincoln, England



CRUDE OIL ENGINE

Uses cheapest grade oil.
Best fuel economy.
Starts instantly from cold.
May we send you catalogue.



Welldeck Steam Trap

(Standard Type)

Suitable for 150 lbs. pressure. Cannot get out of order. Price reasonable.

Stock in Montreal
Made in England.

AGENTS:

LAURIE & LAMB, BOARD OF TRADE BUILDING **MONTREAL**

Designed To Withstand High Pressure

The Mueller Composition Disc Globe Valve is built for the hardest kind of steam line service. Thickness and weight come where strength is most needed.

The threads are full length and tapered. The Mueller Composition Disc used in this valve enables it to withstand high pressure and high temperature. This valve is so constructed that it can be repacked without shuting off the steam.

Scientifically designed by engineers with years of experience and manufactured from the finest materials by expert workmen, Mueller "Globe A-3006" will give years of efficient and economical service. Send for a sample.

Clean Washed Air Means Clean Cool Generators

Heat and dust are the enemies of generators and motors.

Dust produces an overheated condition. Collecting on windings and in air spaces it partially insulates against proper heat dissipation. Add to this a hot stagnant atmosphere, and overheating is inevitable.

Clean, cool air is the remedy for overheating of electrical apparatus. Canadian Sirocco Air Washers supply cool air in any needed quantity—air that is passed through a blanket of finely divided mist that rids it of dirt and dust, and cools it to a degree that insures efficient operation of the generators and motors.

Bulletins of interest to producers of electrical power, describing various types of Canadian Sirocco equipment, will be sent upon request.

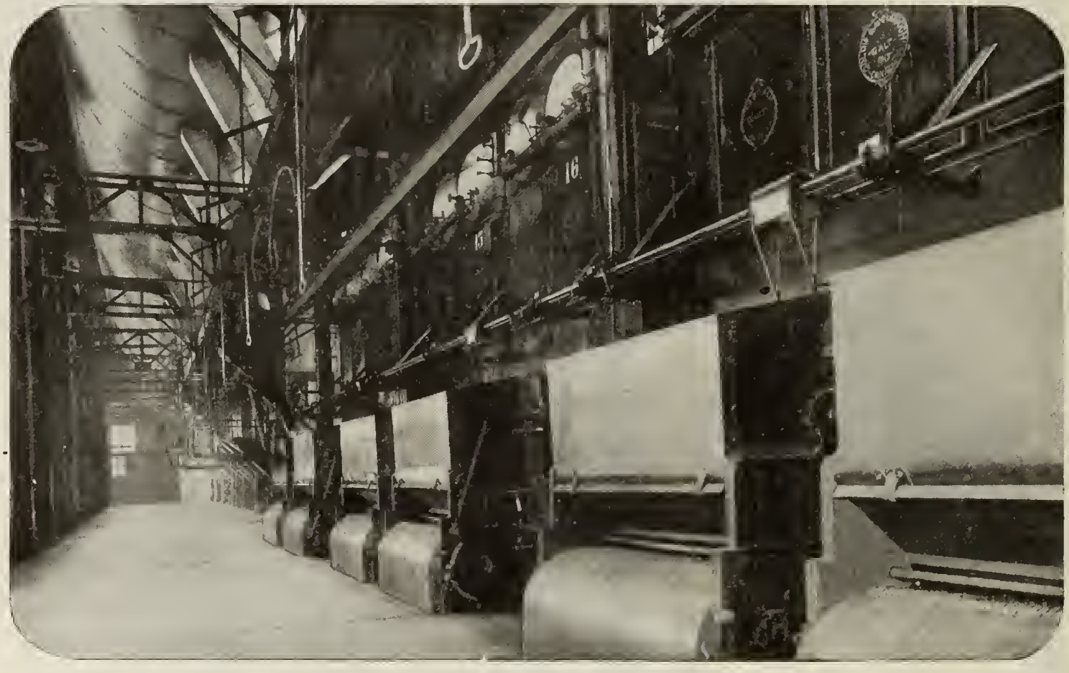
Dependable Power Plant Equipment

G. & McC. Water Tube Boilers
Built for Rapid Steaming



The rapid-steaming qualities of Goldie & McCulloch Water Tube Boilers and their ability to withstand steam fluctuations from nominal to peak loads without strain make them particularly adaptable to plants where the service is variable and at certain periods extremely severe.

Illustration shows boiler room at the Sarnia plant of the Imperial Oil Company. Equipped with 6 G. & McC. Co. Sec.-Type "B" Water Tube Boilers. 10 of the same type are installed at their Dartmouth, N.S., plant and 2 at Regina. 18 in all.

The following statements in a letter recently received from Mr. Montgomery, their Chief Engineer, speak for themselves:—"I am pleased to advise that our experience with these boilers has been very satisfactory. We are able to operate them at very high overloads, exceeding, at times for quite long periods, 200 to 225 per cent. rating. They have in every way been up to our expectations."

Determining Boiler Operating Factors

Discussion of the Methods Used to Determine the Essential Factors for the Economical Operation of Boiler Rooms—Results of Tests Given—Method of Calculating Combined Efficiency of Boiler

By D. C. HESS, Philadelphia, Pa., Stoker Engineer, Service Department, Westinghouse Electric and Manufacturing Co.

RECENTLY there has been a radical change in the method of operating boiler plants equipped with Underfeed Stokers. There were times when it appeared to be common practice to drive all the boiler units in service at their maximum rating without regard for operating economy or maintenance costs. There are times in the average boiler plant when the sudden demand for steam requires that the boiler be operated at high ratings for long periods has geniod. However, continued operation at high ratings for long periods has generally been recognized as not good engineering practice because of subsequent low operating efficiency, economy and increased expense of maintenance.

Combustion Rates and Efficiencies

There is a certain combustion rate where the stoker and boiler operate at their highest efficiency. This can be determined by running a series of short tests at various rates of combustion, and therefore an effort should be made to run as near this point as possible. However, usually this can not be done because, in case of a new plant, the designing engineers have to consider various elements such as first cost, labor, etc. In the case of old installations, it will often be found that the load demand upon the station has outgrown the station, with resultant high capacities. In this discussion it should be considered that the plant will operate at the highest efficiency point, for if the plant operates at any other point, the same discussion holds good but in a lesser degree.

Figure 1 shows the result of a series of tests using Illinois coal in a 6-retort Westinghouse Underfeed Stoker and a 558 horsepower boiler. The grate area was 105.66 square feet. A rating of 328 per cent. was obtained. The unit operated most efficiently at 160% of normal boiler rating, when burning approximately 3,300 pounds of coal per hour, 550 pounds per retort, or 31.2 pounds per square foot of grate surface.

Fig. 2 shows the results of a series of tests run with Pittsburgh district coal. Each 650 horsepower boiler had a grate area of 123.27 square feet which was supplied with fuel by a 7-retort Westinghouse Underfeed Stoker. The best efficiency was obtained at 185% of normal boiler rating. It is also interesting to note the similarity between the combined efficiency CO_2 curves of this test. There was a gradual rise in the flue gas temperature as the boiler rating was increased.

Operating Deductions

The results brought out by these tests show the essential conditions which are necessary to maintain the best operation of the stoker equipment. The point of highest combined efficiency for the first installation is 160% of rating, while the second equipment, the best efficiency, was obtained between 170 and 185% of rating.

The operating force in this plant has found that they can force this equipment to 328% of rating if necessary. The condition of the furnace after a high rating test will determine the effects of the high temperature on the furnace walls and stoker parts.

Stoker Drive

The type of stoker and fan driving equipment should be determined by the heat balance of the entire plant. If

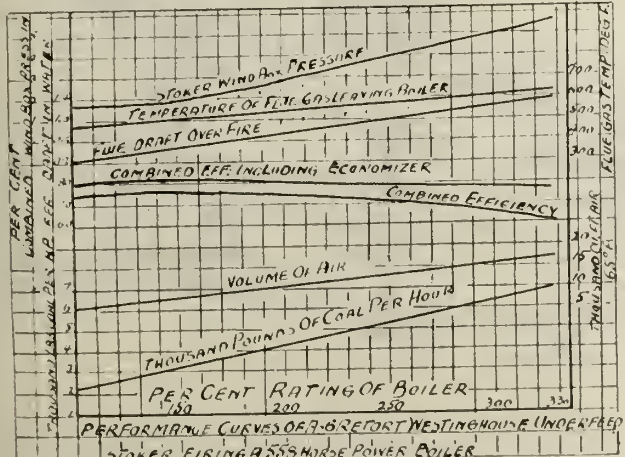

Figure 1.—Performance curves of a six retort Westinghouse Underfeed Stoker and 558 horsepower boiler.

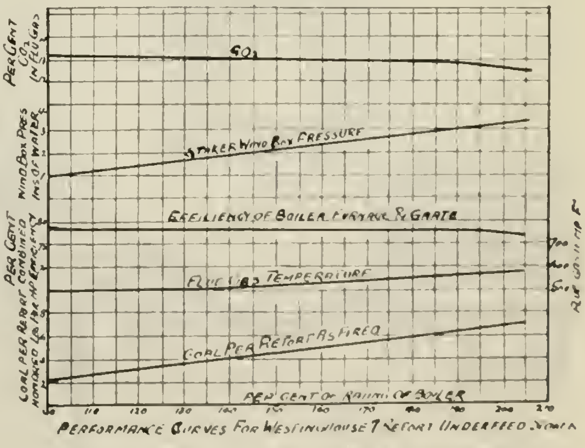

Figure 2.—Performance curves of a seven retort Westinghouse Underfeed Stoker firing a 650 horsepower boiler.

additional exhaust steam is required for feed water, engine or turbine drive will be preferable from an economy standpoint. On the other hand if plenty of exhaust steam is available it might be preferable to use motor drive.

Prevention of Clinker Formation

Clinker trouble is usually not so pronounced in most Underfeed stoker installations until high ratings are reached, and high furnace temperatures are being maintained. If the coal being used contains a low fusing ash, it is evident that clinker trouble will be encountered. Clinker in the fuel bed is hard to avoid, and in cases where they do not move to the rear with the movement of the fuel bed, a hook or slice bar has to be used. Recent changes in the design of boiler bridgewalls tend to decrease furnace temperature and with it to some extent the formation of clinkers. This is accomplished by sloping the front surface of the bridgewall backward so that the rays of heat impinged upon it reflect directly into the boiler tubes and not back into the fuel bed. Also, the latest engineering practice is to expose all tube surface possible to the fire, thereby decreasing the furnace temperature.

In some plants side wall and bridge wall clinker troubles are avoided by the use of steam jets. On the other hand many plants are using side wall tuyeres in connection with Underfeed stokers. These side wall tuyeres are cast iron air boxes which extend above the side retorts and down the side walls.

They are rectangular in shape and fit closely together, but allow room for expansion and contraction. A large cored central space feeds air to the holes in the surface. The air issues at right angles to the wall or tuyeres face. At plants where these side wall tuyeres are in use the side wall clinker trouble has been entirely eliminated, also the life of the boiler walls has been considerably increased. While the maintenance of the tuyeres is very low, due to air cooling the metal, stokers equipped with these tuyeres burn high ash western coals and low ash western coals equally well. Several furnaces have been in operation over three years with very satisfactory results. The air admitted through these side wall tuyeres has little or no effect on the CO_2 as the air is admitted below the surface of the fuel bed, and serves as an aid to complete combustion.

Figure No. 3 shows an installation of the side wall tuyeres.

Instruments Aiding Efficient Operation

Central station engineers are fully aware of the necessity for supplementing an expensive boiler plant with a few reliable instruments that are absolutely necessary for efficient and successful stoker operation. This does not mean that an elaborate set of instruments is necessary, but every boiler plant unit should be equipped with draft gauges for measuring the pressure of the air; in the windbox, in the combustion chamber and in the last pass or in front of the stack damper. A recording or indicating CO_2 apparatus is also desirable for close combustion regulation.

Steam flow meters are extremely valuable boiler appliances. The use of such equipment gives a good check on the combined efficiency of the boiler and stoker.

The ability of the coal to ignite and burn readily in the grates is quickly determined by such actual operating tests. Moreover, such tests have repeatedly proven that very good results can be obtained from cheap coal. The proper ratio between the rate of coal feed, and approximate air pressure for various grades of coal will be quite evident after a series of such tests, at different ratings.

Pyrometers are valuable for determining the flue gas temperature. A high stack temperature means that a relatively small amount of heat is being absorbed by the tubes. This is caused in most cases by defective baffling and dirty tube surfaces. Also a balanced draft in the combustion chamber decreases the infiltration of air through the setting, which is conducive to higher efficiency. Power plant engineers have taken time to study the theoretical side of combustion from its economy standpoint and have saved thousands of dollars each year in the fuel alone. They understand just what a two or three per cent. increase in CO_2 means. Also, the greater evaporation per pound of coal by keeping the flue gas temperature at its lowest possible point. The result in dollars and cents has been most gratifying.

Figure No. 4 shows a CO_2 record for 24 hours operation, the average value being about 12.5 per cent. While Figure No. 5 shows a chart with an average CO_2 content of 14.5 per cent. on the same unit. These CO_2 charts were made at a Western Pennsylvania steel plant. They certainly tell the story to the management, who can quickly judge the best firemen. Also which unit is getting the best results. Note the CO_2 drop at each fuel bed cleaning period, which is caused by excess air being admitted through the side doors and dump grate openings. This emphasizes the advantage of the mechanical steam dump which aids the operator in cleaning the fires quickly. Dampers are provided on the dump grates of the stokers under consideration, to prevent an excess of air from being admitted up through the dump grates at cleaning periods. These damp-

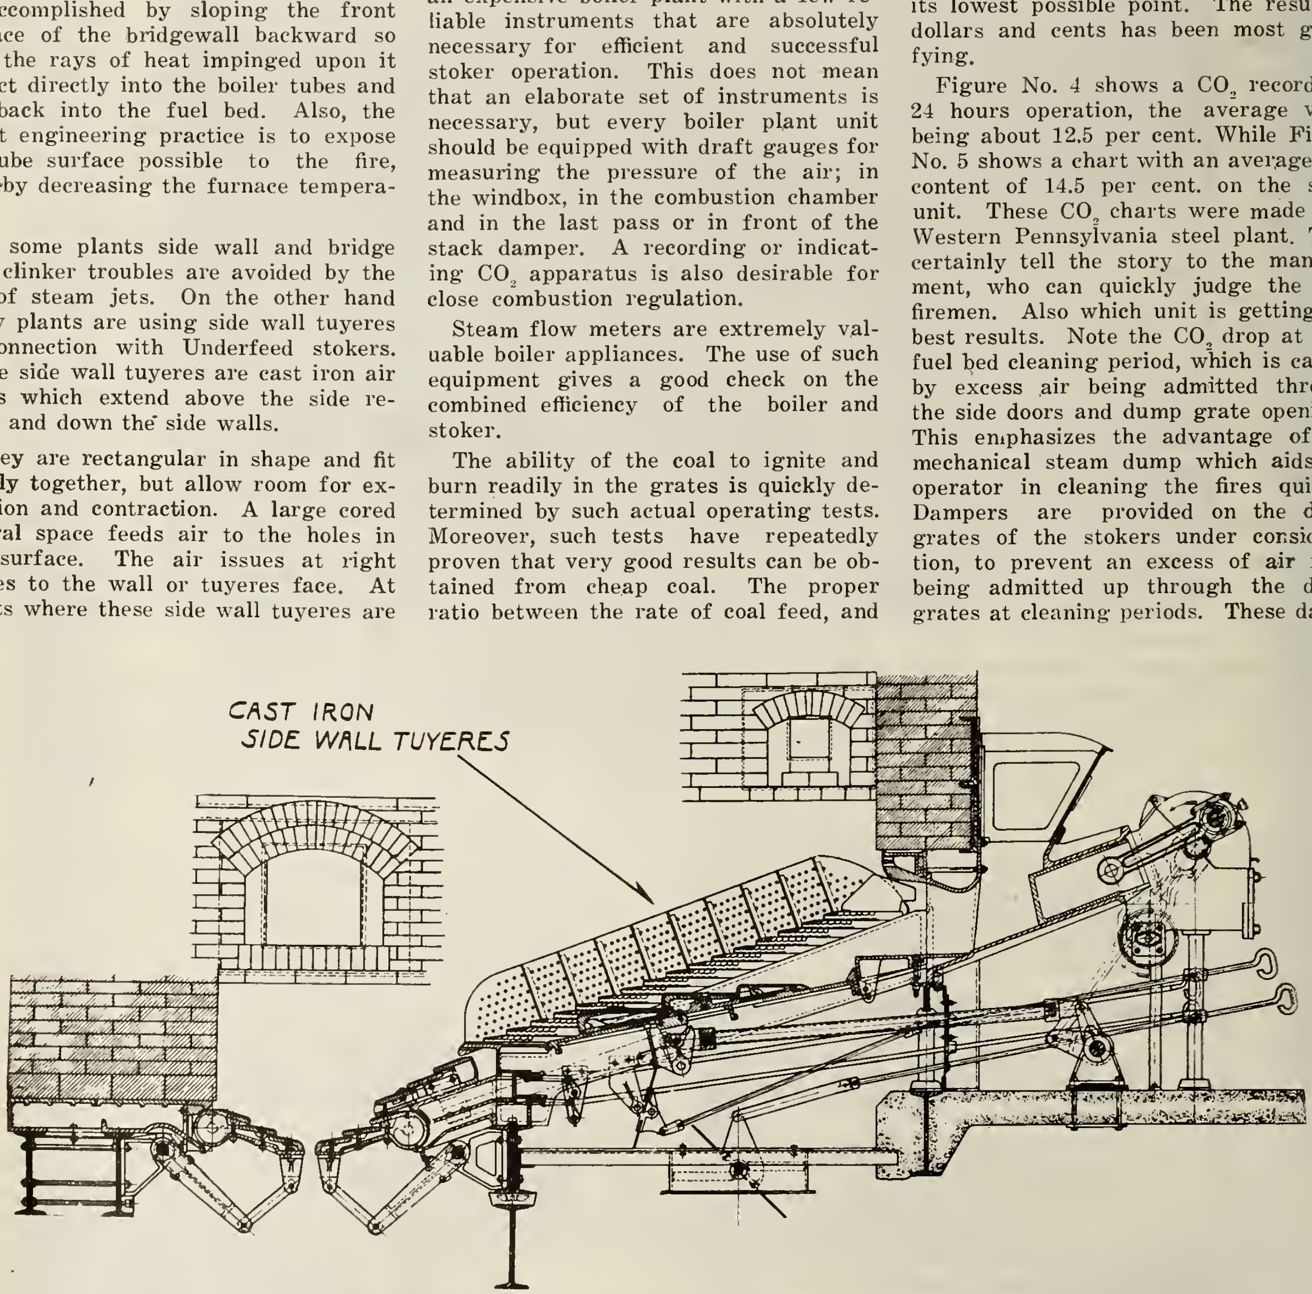

Figure 3.—A double dump moving grate 17 tuyere Westinghouse Underfeed Stoker with side wall tuyeres.

ers are opened to burn excess fuel on the dump grates, thereby increasing the combustion rate and reducing the carbon content in the refuse. In comparing the two CO_2 charts you will note that there is 2 per cent. difference between the average of figures number 4 and 5. This is, approximately 2 per cent. fuel loss in the operation of the stoker from which Figure 4 was taken. This fact emphasizes the importance of the boiler test for setting the operating space.

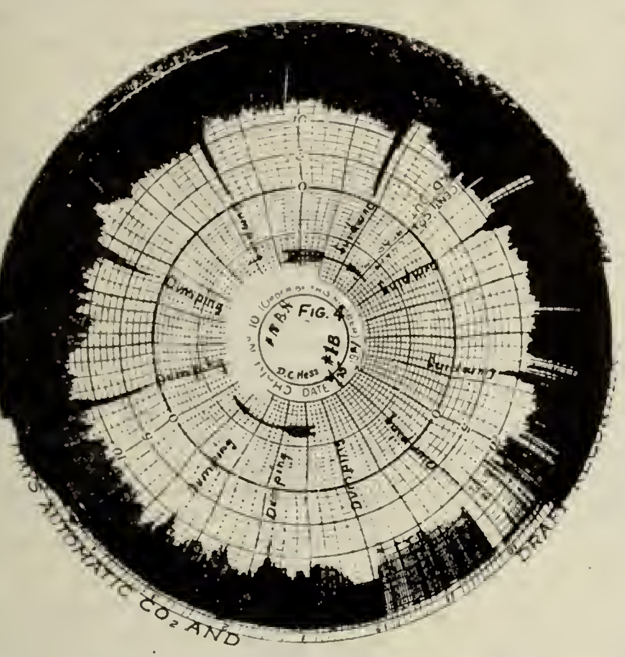

Figure 4.—A 24 hour CO2 chart taken at a Western Pennsylvania Steel Plant, average value of CO2 12.5 per cent.

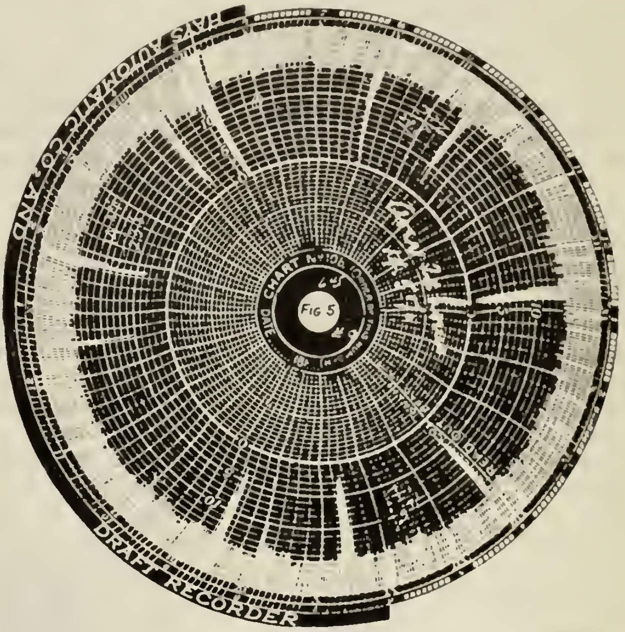

Figure 5.—A 24 hour CO2 chart taken at a Western Pennsylvania Steel Plant, average value of CO2 on the same unit 14.5 per cent.

Three Factors for Firing Furnaces

The principal final product of complete combustion of fuel is carbon dioxide (CO_2). In order to obtain high CO_2 the most important factors to take into consideration are:

First, keep the fuel bed in good condition. That is, prevent the formation of holes in the fire. Maintain the correct thickness and contour of the fuel bed.

Second, eliminate all air leaks in the boiler walls.

Third, maintain as nearly as possible a balanced draft or a slight vacuum in the combustion chamber. Avoid bottling up the gases which would cause a pressure in the furnace. Such a pressure would be very destructive to the brickwork and stoker parts. One type of baffle graduates the cross section of the flue gas passage, so that the velocity of the gas will be uniform throughout the boiler and also eliminate any dead pockets where there is no circulation of gas.

Figure No. 6 is a calculation curve based on the CO_2 per cent. volume at flue gas temperatures of 400° Fahrenheit, 500° Fahrenheit, and 600° Fahrenheit with no carbon monoxide. Theoretically, perfect combustion of pure carbon will give 20.7 per cent. of CO_2 in the flue gases. However, perfect combustion is not possible in boiler room practice.

Referring now to Figure No. 6, suppose the flue gases analyse 6 per cent. CO_2 and that by decreasing the amount of excess air and giving careful attention to the fuel bed the CO_2 is increased to 15 per cent. A glance at the curves shows that the relative fuel loss has been reduced from 40 per cent. to 17, which amounts to a fuel saving of 10 to 12 per cent.

The general definition of the efficiency of an apparatus is the ratio of the energy developed by the apparatus to the energy available for its use.

The efficiencies of the different parts of a boiler installation and of the installation as a whole are defined in so many ways that there is frequently confusion. The following definitions are recommended.

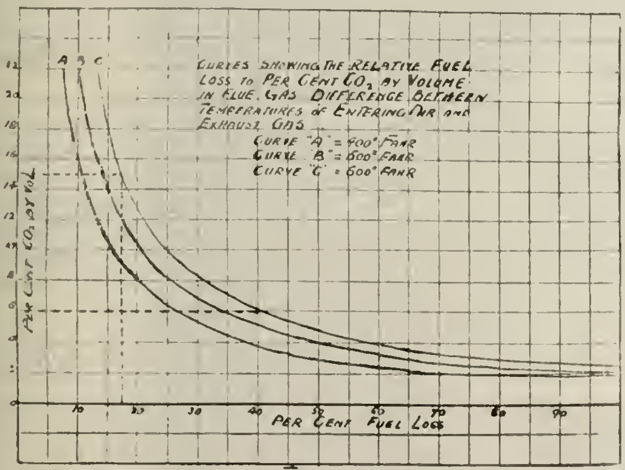

Figure 6.—Calculated CO2 curves based on the per cent. CO2 by volume at flue gas temperatures of 400° Fahrenheit, 500° Fahrenheit, and 600° Fahrenheit, with no carbon monoxide present. Shows fuel saving by increasing the CO2 values.

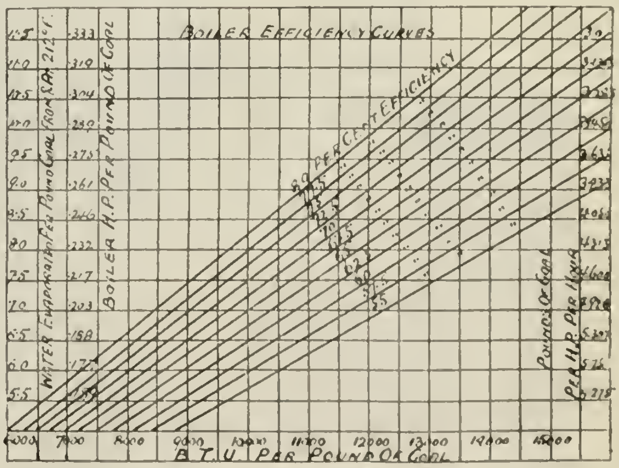

Figure 7.—Combined boiler efficiency curves based on pounds of water evaporated from and at 212° Fahrenheit per pound of coal, of various B.T.U. values.

What is ordinarily called the efficiency of the boiler is in reality the combined efficiency of the boiler, furnace and grate, and is the heat absorbed per pound of fuel divided by the heating value per pound of fuel. The value obtained will be approximately the same whether the efficiency is based on dry fuel or fuel as fired. All the fuel is not burned, some of it goes through the grates or is dumped out with the ash while cleaning the fire. It is obviously unfair to charge this loss to the boiler. On the other hand, the boiler user must pay for it and is justified in charging it against the furnace.

The combined efficiency can be expressed as

$E=W\ (h+L+sS-f)\ DH$

Where W=Lb. of water evaporated in a unit of time.

D=Lb. of coal fired in a unit of time.

s=.48=specific heat of steam.

h=Heat of Liquid at steam pressure.

L=Latent heat.

S=Deg. supt.

h+L+sS=heat in 1 lb. of steam as delivered by boiler.

f=heat in 1 lb. of water as received by boiler.

H=heat value of 1 lb. of coal in B.T.U. as fired.

The numerator of the above fraction equals 970.4 Q, where Q is the factor of evaporation.

Specimen Heat Balance

A typical heat balance worked out according to the above formula is given below:

The calculations are made as follows:

24 hour test of 2,400 H.P. boiler operated at 137% of rating

Coal as fired: 76.87% Carbon; 5.31% Hydrogen; 7.19% Ash; 1.80% Moisture; 13,810 B.T.U. per lb.

Dry Coal=98.2% of coal fired.

Dry coal basis: 78.30% Carbon; 7.32% Ash; 5.41% Hydrogen; 1.83% Moisture; 14,090 B. T. U. per lb.

Coal fired 246,000 lbs.=241,500 lbs. dry coal.

Refuse produced 21,375 lb.=8.88% of dry coal.

Carbon in refuse=8.88—7.32=1.56% of dry coal.

This statement assumes that all of the ash is in the refuse.

Flue gas analysis: 14.6% CO_2, 0.36% CO, and 3.30% O_2. CO is seldom found in the products of combustion but if produced it is treated as follows in the heat balance.

Water evaporated, 2,480,000 lb. steam pressure 160 lb. gauge, superheat 100°=1,254 B.T.U. per lb. above 32°F.

Average temperatures: Feed water 220° Fahrenheit, flue gas 560° Fahrenheit, room 72° Fahrenheit, air 63% saturated.

Heat Balance Calculations

	B.T.U. per lb. dry coal	% of total heat
1. Heat absorbed by boilers: 2,480,000 (1254—(220—32)) /241,500	10,960	77.79
2. Heat lost by evaporation of moisture in coal: 0.0183 (212—72+970+0.47 (560—212)	23	0.16
3. Heat lost in steam from hydrogen in coal: 9 x 0.0541 x (212—72+970+0.47 (560—212))	609	4.32
4. Heat lost in dry flue gases: Air = 3.036 (0.7830—0.0156) (1—0.1460—0.0036—0.0330) / (0.1460+0.0036) = 12.45 lb. per lb. of dry coal. Gases 12.45+(1—0.0888) =13.36 lb. per lb. dry coal. Loss=0.24x13.36 (560—72)	1,565	11.10
5. Heat lost in unburnt CO = (0.7830x10,150x 0.0036) / (0.1460+0.0036)=	193	1.37
6. Heat lost in combustible refuse = 14,600x 0.0156 = ...	246	1.75
7. Heat lost in heating moisture in air—63% at 72°F.= 0.0168 x 0.63 =0.0105 lb. per lb. of air (0.0105 x 12.45 x 0.46 (560—72)=	29	0.21
8. Unaccounted for (Radiation, unburned hydrocarbon, errors of observation) by difference=	465	3.30
Total	14,090	100.00

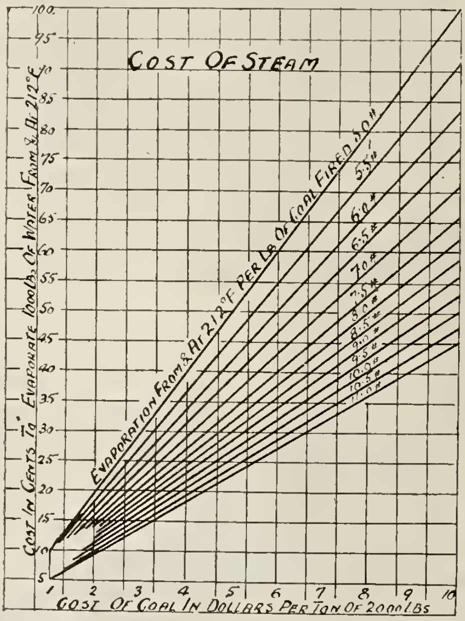

Figure 8.—Cost of steam based on the pounds of water evaporated from and at 212° Fahrenheit per pound of coal fired.

Figure No. 7 is a set of curves showing combined efficiencies based on pounds of water evaporated from and at 212°Fahrenheit per pound of coal of various B.T.U. values. These curves also give the boiler horse power per pound of coal and pounds of coal per housepower per hour.

Cost of Steam Curves

Figure No. 8 is a set of curves showing the cost of steam based on the pounds of water evaporated from and at 212° Fahrenheit per pound of coal fired. The column at the left shows the cost in cents to evaporate 1,000 pounds of water which is plotted against the cost of coal in dollars per ton of 2,000 pounds.

"The Three Graces"

After you have made a thorough study of your boiler room conditions and heat balance, you will no doubt come to a final conclusion that the economical operation of your boiler plant narrows down to three things.

First, maintaining high CO_2. This means good combustion of the fuel. This is accomplished by keeping the proper ratio between the fuel feed and air supply, good fuel bed conditions and careful attention to the operation of the stokers and boilers.

Second, keeping the flue gas temperature as low as possible. That is, absorb all the heat possible from the furnace gases before they reach the breeching.

Third, reducing the combustible in the refuse as low as possible. This signifies good operation on the part of the fireman, who should control the fuel bed conditions so that a minimum amount of carbon is dumped with the ash.

These three items are the main factors in boiler room operating from an economy standpoint.

TO BRIGHTEN TARNISHED BRASS AND COPPER

To brighten tarnished brass and copper clean the brass by warming it, and dipping in water charged with washing soda, then into clear water to remove the grease. Next dip it in a bath of one part sal-ammoniac, two parts nitric acid, and four parts water. Dip for a moment, then dip in clear water, and dry in hot sawdust. Oxalic acid dissolved in soft water—say, ½ oz. to a pint—is one of the best-known means for cleaning and brightening brasswork. — Mechanical World.

North Vancouver, B. C., will build an addition to the waterworks plant to cost $40,000. G. H. Morden is mayor.

The time for receiving bids on drydock machinery for Esquimalt, B. C., has been extended until Feb. 15. R. C. Desochers is secretary Department of Public Works, Ottawa.

Resumption of work on the Esquimalt drydock at Victoria, B. C., has been ordered by J. H. King, federal minister of public works. The work is expected to be completed about June, 1924, and will cost $1,500,000. Tenders for $500,000 worth of operating plant and equipment will be called for soon.

Water Turbines and Their Principle

A Description of the Forces Involved in Converting Head-Pressure Into Useful Work, and the Means of Effecting This Through Various Types of Turbines and Illustrating Practical Installations

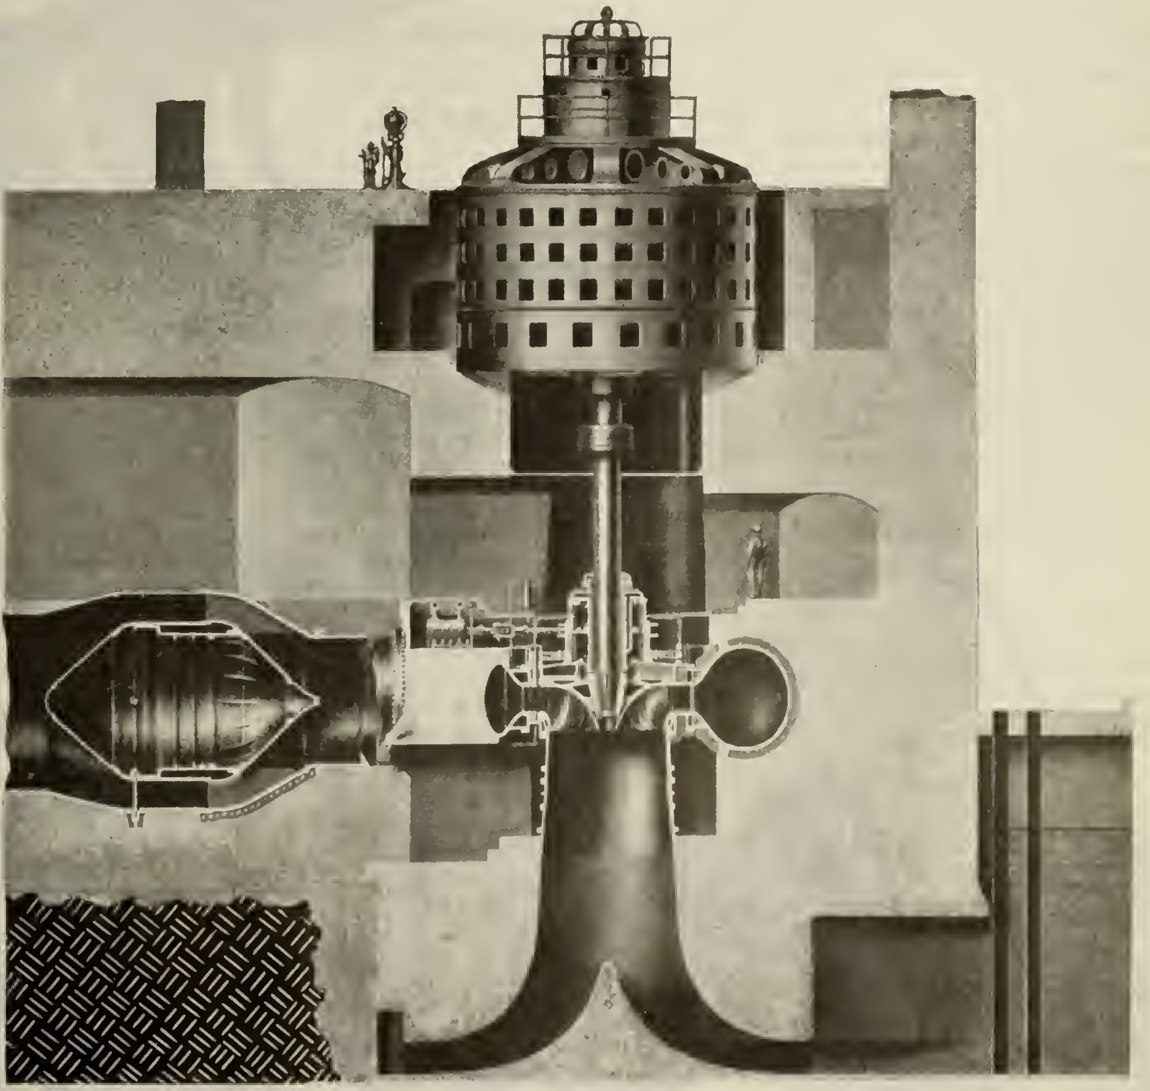
By W. B. ROBERTS, Editor

When we look at the vast natural sources of water power in this country there is little wonder that very special attention is being paid to the machine that is being used for converting this natural energy into useful work. A large number of power plant engineers will always associate the steam engine with the electrical generation of power, although they know that much hydro-electric power is generated. They have perhaps, no idea of the large percentage of hydro-electric power that is generated compared with the total electric power generated throughout the Dominion and it might not, therefore, be out of place to give a few figures, made by the government in 1918, showing the amount of H. P. developed due to hydro power, steam engine and the internal combustion engine.

The electric power developed through hydro was 1,806,618 H. P., compared with 288,202 H. P. for steam, or in other words, nearly seven times as much. The electric power developed due to the internal combustion engine was only 12,923 H. P., which is only a very small proportion of the whole. It will, therefore, be seen that the water turbine is a machine that ranks amongst the principal prime movers in this country and it will no doubt be an interesting study to investigate the development of these machines and understand their application from first principles.

Before we start to deal with any form of turbine, it would be just as well to refresh our memories with some simple facts regarding hydraulics and the peculiarity of water under certain conditions.

The pressure of the atmosphere can be taken to be 14.7 per square inch with a 30-inch barometric height. In a water barometer, the height of water this would support would be 34 feet. If, therefore, we divide this head of water



QUEENSTON-CHIPPAWA DEVELOPMENT.
Cross section through 55,000 horse power unit, the largest in the world, showing generator, turbine, water-supply pipes, valve and draft tube. The enormous size may be judged by the man standing in the gallery.

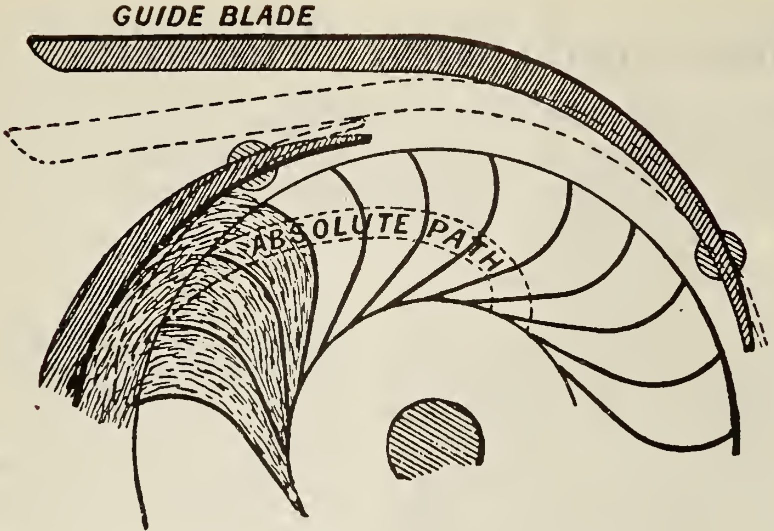


Fig. 1. Diagram of Pressure Turbine.

(34 feet) by 14.7, we will get the height of water corresponding to one pound pressure.

$\frac{34}{14.7} = 2.3$ feet, or 1 lb. per sq. inch.

also a cubic foot of fresh water $= 62.5$ lbs.

and a cubic foot of salt water $= 64$ lbs.

To thoroughly understand the relation between head and pressure, let us consider a tank H high, having an area of A square feet filled with water, with an opening on the side at the bottom, through which the water is allowed to flow at a velocity of V. A water barrel is a typical example of what we mean, with a small bung-hole at the bottom.

Let $P =$ pressure per sq. ft.
$H =$ height of column.
$A =$ area in sq. ft.
$W =$ the weight of water per cu. ft.

Then $P \times A\ W \times H \times A$
or $P = W \times H$ (the A's cancel out).
and $H = \frac{P}{W}$

In other words this means that the weight of water in the tank is equal to the pressure of the water at its lowest point, multiplied by the area.

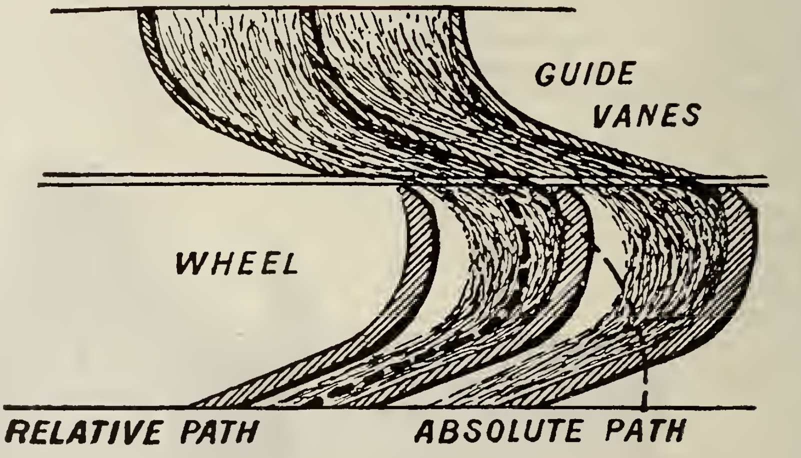

Fig. 2. Diagram of Impulse Turbine.

To show how potential energy is converted into kinetic energy, we will now take a certain weight of water W at the top of the tank and at a height H. By allowing this portion of the water to fall to the level of the hole in the side of the tank, it has performed so many foot pounds of work, and in so doing, has been converted into kinetic energy.

The water in its original position at the top of the tank has, therefore, so much potential energy which can be denoted by the letters $W \times H$.

Kinetic energy is weight or mass multiplied by velocity, similar to the blow delivered with a hammer. The hammer head does not vary in weight, but we all know that a heavier blow can be effected by increasing the speed.

The formula for kinetic energy is $\frac{WV^2}{2g}$

When $W =$ Weight, $V =$ Velocity in feet per second, $g =$ gravity, which equals 32.

Considering, therefore, that the water which was at the top of the tank whilst at rest contained a certain amount of potential energy ($W \times H$), but upon falling through the distance H, it has become converted into kinetic energy

$\frac{W \times V^2}{2g}$ so that

$$W \times H = \frac{W \times V^2}{2g}$$

(the W cancels out and by transposing the formula we get)

$V = \sqrt{2gH}$

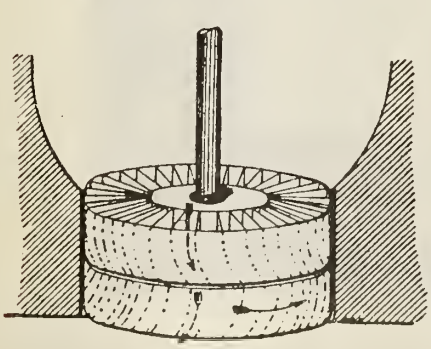

Fig. 3.—Jonval's Turbine.

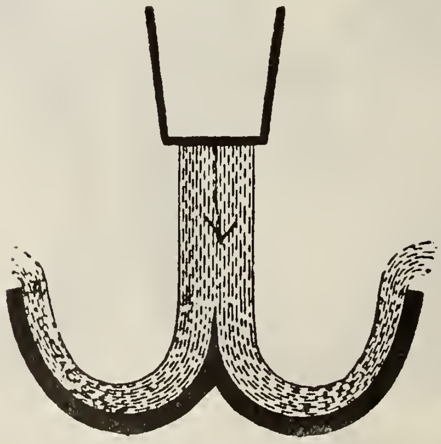

Fig. 4.—Pelton Wheel Bucket.

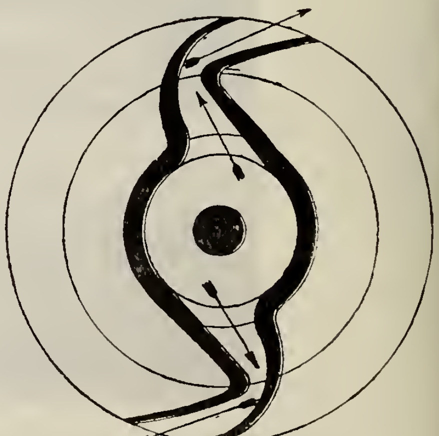

Fig. 5—Wheel with Wide mouthed nozzle.

By looking at the experiment illustrated in Fig. 7 you will see at a glance how pressure and velocity are convertible. The liquid flowing from the vessel A through the pipe C. E. F., must increase in velocity at the contracted portions with a corresponding loss in pressure as seen by the level of the water in the open ended tubes. The velocity of flow is inversely as the size of cross section, and the pressure inversely as the velocity. If, therefore, the difference in height between the level of the water in the tank and the pipe is measured, it will be found to be equal in each case to $H = \frac{V^2}{2g}$ where H is the difference between the pipe levels and tank level.

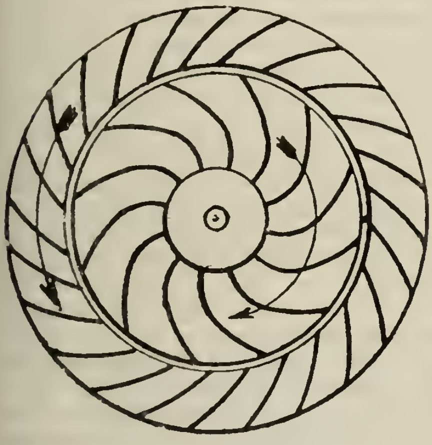

Fig. 6—Combined Pressure and Impulse Turbine.

The illustration of the tank of water can therefore be applied to any practical case, such as the water flowing from a reservoir, or from some high level to a lower level, and in which case the whole head H is expended in three forms.

$\frac{P}{W}$ due to pressure,

$\frac{V^2}{2g}$ due to velocity,

and the combined effects $H + \frac{B}{W} + \frac{V^2}{2g}$

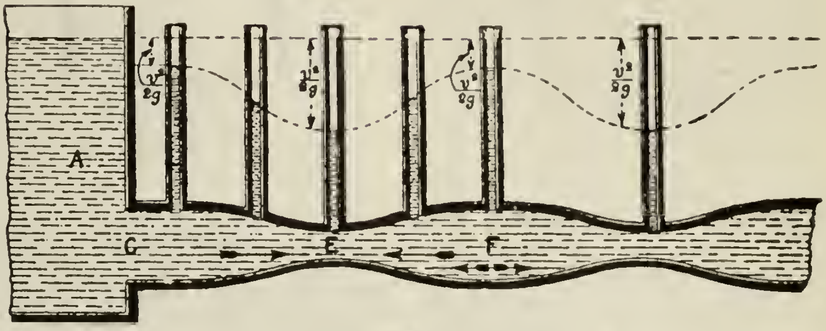

Fig. 7—Hydraulic Experiment.

The turbines that we are now to consider, act either by the first, second or all three forms of energy, but we had better at this point describe a few of the different designs of turbines.

Water turbines are divided into two distinct classes, i.e. Pressure turbines and Impulse turbines. These can be again subdivided into several other classes, such as Axial Flow Turbine—Inward, Fig. 3, Radial Flow Turbine, with water flow from the outer to the inner periphery, Fig. 1, the Outward Radial Flow Turbine, where the water flows from the inner to the outer periphery, Fig. 5, Mixed Flow Turbines, etc., etc., but for the purpose of this article we will deal simply with the first two classes mentioned.

In the Pressure Turbine the rotor acts partly by the pressure of the water and partly by its momentum. The water after it enters the turbine has a certain amount of pressure since the energy due to the fall has not all been converted into velocity. It also has velocity which is given up in the turbine and converted into the corresponding amount of energy.

In the Impulse Turbine, the head of water is converted into a jet of great velocity due to the fall, but these jets have no side pressure.

Water under pressure transmits that pressure sideways, forward, and in every direction, but in a column of water moving at full velocity, there is no side pressure since the whole energy is in the forward movement.

Pressure turbines work best when drowned so that no part of the fall is lost. They will, however, work well up above the tail race if the mouth of the overflow pipe is carried below the surface of the tail water. This facility is of great value since it is not always possible to have the turbine at the level of the tail water. The impulse turbine, however, must be placed above the highest level of the tail water and will not work drowned, hence the whole fall can-

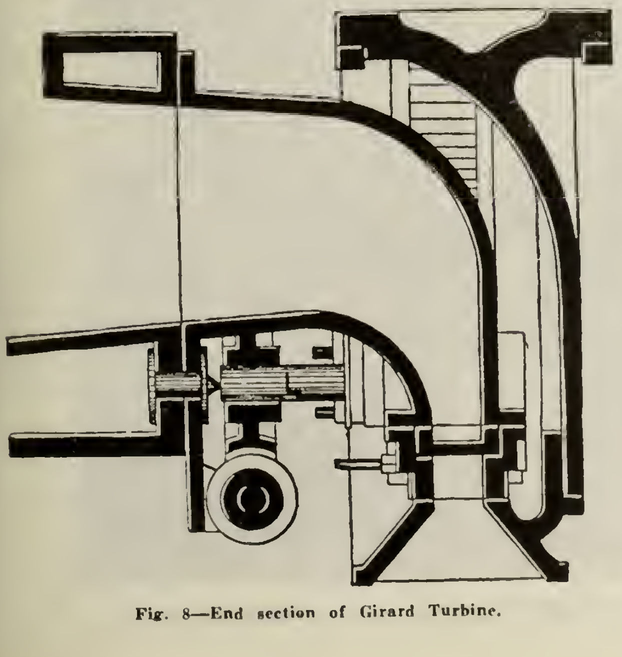

Fig. 8—End section of Girard Turbine.

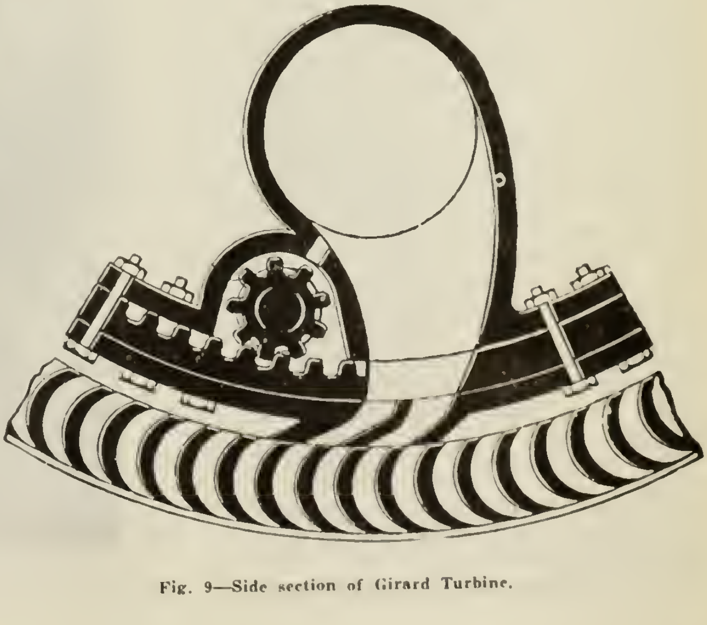

Fig. 9—Side section of Girard Turbine.

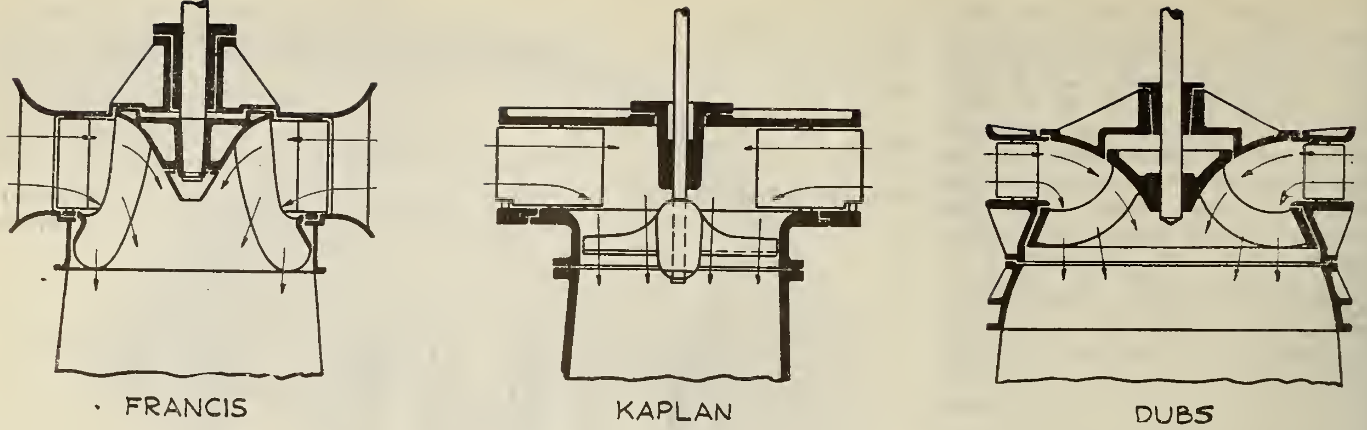

Fig. 10. Types of High Speed Turbine.

not be utilized at low water level in the tail race.

The two forms of turbine are illustrated in Figs. 1 and 2. The turbine in the first illustration is a pressure turbine inward flow with guide plate to give direction to the water and regulate the quantity. Fig. 2 is an impulse turbine wherein the water is spurted at full velocity against the vanes in the wheel. In this turbine there are as many guide plates as buckets and the water may flow full bore all around, but this is not necessary.

The simplest form of impulse turbine is one that is illustrated in most mechanical test books in the form of the Pelton Wheel, illustrated in Fig. 4 and which is driven by a free jet. The wheel has attached to its periphery a series of double cupped buckets. The jet at full velocity strikes the dividing rib, splits in two and glances off the wheel reversed in its motion which exerts great pressure on the cups. The impulse pressure on the turbine blades is equal to the momentum before entering minus momentum on exit.

Although the Pelton wheel gives good results it was not designed with a scientific knowledge of the subject. We understand that Mr. Pelton had a number of cup-shaped buckets on a wheel, one of which worked loose and being displaced relative to the jet, the latter struck the side instead of the centre of the bucket. It was observed under these conditions that the mill driven by this wheel ran faster. From this, it was arranged to fit two sets of buckets mounted on either side of the wheel, the side thrust of one set of buckets being compensated by that of the other.

We understand that an efficiency of 91.85 per cent was attained by Professor Hiccock on a 26-in. Pelton wheel at the engineering laboratory of the Ohio State University in 1897, which was obtained with a head of 163 feet, the flow of water being 2,085 lbs per minute, with a bucket velocity of 46.2 feet per second.

In Figs. 8 and 9 we have a section of a radial outflow turbine, giving view of wheel, guide-blade and passages in the first illustration, and the orifices and nozzles and their means of regulation by a sliding rack and pinion in Fig. 9.

The blades are specially spread out to enable the water to spread as it passes through the passages so that the arc of the outer passages is somewhat greater than that of the inner. The ratio of the radius of these passages should be about 1.18 to 1. The efficiency is about 75 per cent. when Q = 240 cubic feet per min. h = 400, the weight of one cubic foot of water = 62.5 lbs.

$$\frac{75\% \text{ x Q x h x } 62.5}{33{,}000} = \frac{.75 \text{ x } 240 \text{ x } 400 \text{ x } 62.5}{33{,}000}$$

$= 130$ H.P.

The transformation of the turbine now in progress has developed within recent years to such a point that the designer of a hydraulic plant to-day has a much larger form of turbine to select from than ever before, which numbers also enlarge for him the field of possible error. In order that some of the new turbine types under an increasing range of heads may be studied, some of the high speed turbines now proposed or already applied, are shown in the three diagrams in Fig. 10. These compare the ordinary "Francis" turbine with one of the forms proposed by Dr. Kaplan of Austria, also one developed by Dr. Dubs of the Escher Wyss Co., which is an extreme development of the "Francis." The "Moody" diagonal propeller type turbine is illustrated in Fig. 11.

It will no doubt be of interest at this point to look over the general arrangement given in the illustration of the

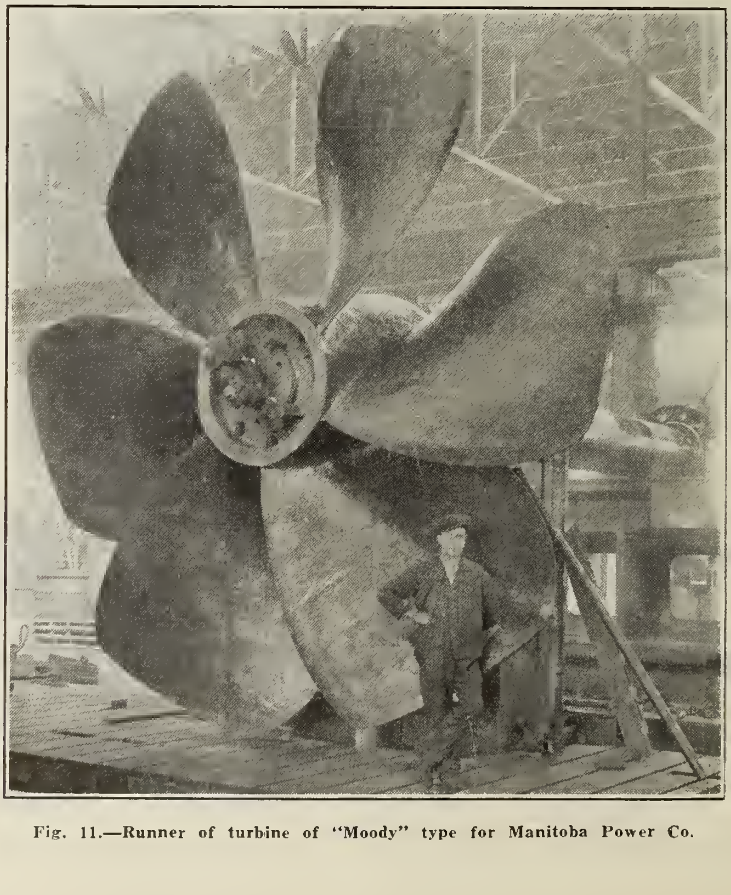

Fig. 11.—Runner of turbine of "Moody" type for Manitoba Power Co.

pump-house and turbine of the Chippawa development at Niagara which shows the practical application of a head of water and the means of converting this into useful work.

The turbines are each of 50,000 h.p. rated capacity and of the vertical spiral case, single runner Francis type and will operate at a speed of 187.5 r.p.m. This gives a specific speed of 36. The maximum guaranteed efficiency is 90%. The inlet diameter of the scroll case is 10 feet and the diameter of the runner is 10 feet 5 inches at the inlet. An open space has been left in the power house foundations below the runner so that by removing a section of the draft tube the runner can be taken out from below, thus obviating the necessity of dismantling the generator when renewal of the runner is necessary. The runner is designed for a capacity of 61,000 h.p. and is "gated back" to a maximum capacity of 55,000 h.p. The reason for this is that the turbines, which will normally operate at or near full rated load, will, therefore, also operate at their maximum efficiency. The total effective head of water is 305 feet and the installed capacity of 9 units will give a total of 500,000 h.p.

ELECTRICAL EQUIPMENT

It might be of interest at this point with a view to giving a better conception of the tremendous size of each unit, to give a few particulars of the electrical equipment, the generators for which are the heaviest in the world.

The entire weight of the revolving parts of each generator and turbine is carried on a thrust bearing which is designed to sustain a weight of one million pounds. The heaviest part of the generator weighs 300 tons and its removal requires the use of two 150-ton cranes installed in the power house for this purpose. The generator is air cooled, which air may be taken either from inside or outside the generator room. It generates electric power at 12,000 volts, the frequency being 25 cycles. This is transformed to 110,000 volts before it is transmitted down the lines in the different directions.

Manitoba is also pushing ahead with the development of her natural resources in the province. Last month the Manitoba Power Co. had the official opening of the first unit of the power plant at Grand Falls. We understand the unit now completed and in operation is designed to deliver 28,000 h.p., but until the second unit is ready for operation the power actually developed falls somewhat short of the above amount as the full head of water cannot be utilized. The illustration given in Fig. 11 shows the runner for the first unit. This is a Moody diagonal type runner weighing 74,000 lbs., 15 ft. 9½ in. in diameter, and the boss or hub being 4 ft. 5¼ in. deep. This is a cast steel runner and the first of this type to be ever cast in Canada. The most striking difference between this type of runner and the Francis which has held the field for so long for medium and low head installations, is the speed. The rim speed of the new runner is about 7,000 ft. per minute, or twice the velocity of the water under a head of 56 feet, from which the units are to be worked. In comparing the r.p.m., we understand the new runner has a speed of 138.5, while a Francis runner of the same capacity and under similar conditions would run at 75 r.p.m. The greater speed means a smaller generator, smaller cranes, lighter overhead construction and a very material saving throughout the whole of the installation.

Improvements in Design of Friction Clutches

Eliminating Power Loss—Characteristic of Various Types—Cone Clutch Not Suitable for Heavy Load—Advantages of the Plate Design—Effect of Centrifugal Action

By V. R. BRUCE, Manager, Hilliard Clutch and Machinery Co.

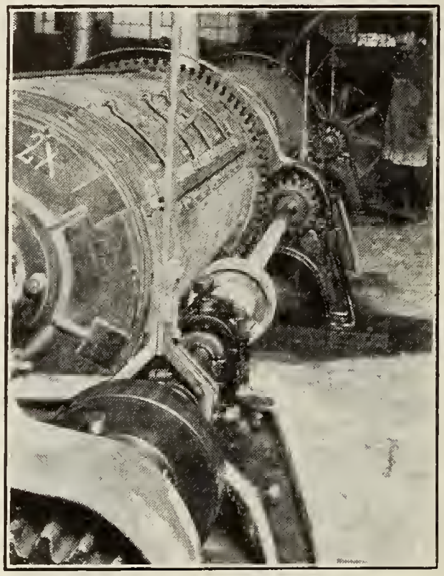
EFFECTIVE solution of power transmission is a problem that requires close attention of plant executives in order to avoid the loss incidental to poor and inefficient installations. In the accompanying article are given the relative merits of various types of clutches and what, in the judgment of the writer, are some of the installations practical with clutches which reduce the plant equipment upkeep to a minimum and place the manufacturer in a position to meet modern competition.

In the first place, it might be stated that friction clutches could be generally classified as follows: Cone, expanding shoe, contracting band and plate type clutches. Cone clutches are used to some extent by some machinery manufacturers for countershaft purposes. The characteristic of all cone clutches is that they take hold very quickly and are certainly not a type of clutch that should be used for picking up heavy loads smoothly or gradually. As a rule when applied to machine tool drives, it is a metal to metal friction.

The expanding shoe clutch is made up in a great many variations having several different methods for expanding the shoes which grip the outer driven member which is usually in unit with the clutch sleeve. The troubles characteristic of the expanding shoe clutch are also characteristic of the contracting band clutch, resulting in overstraining and breakage of the operating mechanism, grabby action, failure to properly release, and also a tendency to drag just as soon as the sleeve members are slightly worn which permits the outer friction member to drop down for the small distance allowed for the clearance between the driving and driven members. The slightest amount of wear in the clutch sleeve will permit contracting band or expanding shoe clutches to drag.

Judging from the various types manufactured, it would seem to be the consensus of opinion that the plate type clutch properly constructed, is the better unit for all practical purposes. The exceptions that we would make would pertain primarily to very heavy duty clutches, in which case contracting and expanding shoe clutches can be made up in very much larger sizes and have very much less weight to them than is possible with any kind of plate clutch. So when we get into very large horsepowers it is probably true that a clutch along the lines of the expanding shoe type might be excepted.

However, for small drives ranging from 2 h. p., say up to 100 h. p., it is our judgment that the plate type of clutch is superior. Our reason for saying it is superior is that it can be kept to smaller diameters, have greater friction area for any given diameter, permits of a type of operating mechanism, which does not involve the usual troublesome toggles and permits of a larger friction area for any given diameter, with a resultant lower unit pressure on the frictions, and therefore longer life and less frequent adjustment of the clutches.



Installation of plate type clutches on gang of foundry cleaning mills.

It is likewise necessary to make some distinction between plate type clutches.

We substitute for the toggle operating mechanism three worm threaded studs which are actuated by means of a spiral gear and rack which in turn are actuated by a sliding collar, and this permits the full pressure to be exerted on the friction surface. With toggle clutches the full power is never exerted because the full pressure is used in passing the center, and it is necessary to pass the center in order to lock the clutch, and this causes a slight releasing of the clutch. This involves an overstraining and a frequent breakage of parts.

In order to get past the center with toggle type clutches it is necessary to go past quickly, with a sudden jerk, and that, of course, is disastrous to any type of delicate machinery. With worm threaded studs it is easy to pick up a load gradually and as smoothly as desired and to provide considerable reserve of travel on the operating racks; each tooth in reserve on the racks is the equivalent of an adjustment of the toggle type clutches.

With all plate clutches the sleeve bearings can stand a great deal more wear, without interference with the proper operation of the clutch, than is possible with any type of expanding or contracting shoe. You can readily see that the plane of the friction surfaces is at right angles to the shaft and therefore there is much less chance for dragging as wear occurs than with other types in which the friction faces are parallel to the shafting.

However, to absolutely insure correct alignment and very long life to those clutches, we have improved the bearing conditions in the past few years by the use of ball and roller bearings; particularly our clutches equipped with Fafnir

Some Hints Upon Running Oil Engines

Treating With the Care and Management of the Diesel Engine—Means of Determining Distribution of Load—Analyses of Working by Reference to Indicator Diagrams

By B. BARE

WHILE almost all the high-compression types of engines can run on anything that can be called an oil, it is a question that must be decided in each case whether it is worth while to use the low grade of fuel, or whether it is better to use what is known as a "Diesel oil." Some of the largest motor-ships that have reported perfect voyages and where these voyages have been half around the world, have used a "Diesel oil." In cases like this, where the load factor on the engines has been very high, it would be the most desirable to use the cheapest fuel. It may be that a better grade of fuel is cheap enough. It is true that the high-compression engine will give perfect satisfaction when running on the heaviest fuels, but it means that there must be extra care and attention given in such cases. It is very important to have efficient and careful engine-room personnel when these heavy fuels are used. In the future the cost of fuel will advance and it will be more economical to use the heavier fuels and pay a little more for the engineer who can keep his engine in the proper condition.

STARTING WITH HEAVY OIL FUEL

Besides heating the heavier fuels, as has been mentioned, it is particularly necessary to keep the passages clean and free from "gumming" which the heavy fuels are inclined to cause. Filters of ample capacity fitted in the fuel-section line, and of a type that allows continuous operation of the engine, are desirable. A very fine mesh screen should also be fitted in the delivery line, as the passages, especially in the mechanical-injection types of engine, are very small, and a particles of dirt in the nozzle will give trouble.

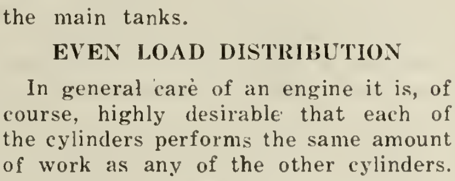
Kerosene is the engineer's best friend in the case of gumming. When starting up cold, kerosene should be used until the engine has become warmed up well and the heavy fuel ready to be turned into the line has also had a chance to warm up. Five minutes will be long enough for this, then the heavy oil can be turned into the line through any three-way-cock arrangement. Where air injection is used a little change in injection-air pressure may be needed. Increase the pressure until there is the tendency to "knock," and then reduce the pressure just enough to prevent the engine from labouring. In plants where the engine is shut down at noon, the kerosene should be used for about 5 mins. before stopping. This will give time to clean out the engine and fill all the piping and the valves with this lighter fuel. In this way there will be no sticking of the parts should the engine get cold.

Where there is continuous running it will be well to run on kerosene for about 5 to 10 mins. once each watch. The kerosene will tend to loosen any deposit that tries to form and burn it out, just as it does in the case of the gasoline engine. It will also be well to squirt some kerosene down the exhaust-valve stem to keep it from getting sticky, and to clean the exhaust valve seat. This should be done on each round of inspection. Whenever the engine is shut down for a considerable period the fuel-pump valves should be filled with the kerosene.

When using heavy fuel particular care should be taken to have the fuel as free from water as possible. It is quite sufficient to let the fuel stay in the main supply tanks, where the water can settle to the bottom and be drawn off. For this reason, as well as to allow a place for the sediment to settle, it is well to have the outlet from the main tanks at a little elevation above the bottom of the main tanks.

EVEN LOAD DISTRIBUTION

In general care of an engine it is, of course, highly desirable that each of the cylinders performs the same amount of work as any of the other cylinders. By listening to the exhaust a rough estimate of the amount of work being done by each of the cylinders can be ascertained. A favourite method with low-compression engines is to open a pet-cock, usually that used for indicating, and listen to the explosions. At first a little time must be given the communicating hole to clean itself out, and then by getting all the explosions to sound alike, a fairly good distribution of load will be obtained. This method is also a quick and positive means of identifying a "missing" cylinder.



Oil-engine Hints.—Fig. 1.

Use of the indicator card is, however, becoming more common, and will give the finer distinction as between loads. Where the engine is equipped with the mechanism for conveniently taking indicator cards, and where the installation requires the constant services of an operator, cards should be taken once a week as a matter of routine. In this way a small irregularity will be quickly detected and correction can be made before any trouble occurs. The cards must be taken when the load on the engine is constant, otherwise it will not be possible to tell whether the difference in card readings is due to the variation between cylinders or to the variation in load during the period of taking a set of cards.

Cards should be inspected first for similarity of shape. If the shape of the card is found to be good, or if it has been brought to this condition, the next thing to do is to measure the area of the card to determine the load the card represents. The area of the card represents, of course, the amount of work done by the cylinder from which the card was taken. The best way of obtaining the area of a card is by means of the planimeter. The areas of all the cards should be made equal by adjusting the fuel to each of the cylinders as provided for on the engine, either through a distributor where such is employed, or by separate adjustment where there is a plunger for each cylinder.

OVER-PRESSURE

When looking over the individual cards, the point of top dead centre should be particularly noted. The pressure at this point should not exceed that for which the engine was designed. Where the engines are subject to inspection by the insurance companies, that pressure must not be exceeded. When the engines are put out at the factories the cylinders and heads are tested at a pressure about one and a half times the maximum operating pressure, so it is important not to be operating the engines at a higher pressure than that tested for by the inspectors. Relief valves are fitted to the cylinders, but the passages are generally small and will not take care of any great volume. Their function is mainly in the nature of a warning that the pressures are being exceeded. These valves are also fitted for hand operation, and it is well to open them once a day to let any accumulation in the connecting passage blow itself out. It sometimes happens that the accumulation of deposit has become so hard that it is necessary to drill into the hole to clear the passage. Do not let the pressure cause the valve to blow out continually, because the heat from the cylinder at the time of blowing is very great, and it will not take long to burn out the valve or seat and cause trouble.

In the indicator cards where the maximum pressure is greater than the pressure at the end of compression, the explosion line is best when vertical. If this cannot be obtained it is better that the explosion line incline away from the head end of the card rather than that the fuel be injected too early (Fig. 1). In the case of air-injected fuel, the compression is also the maximum, and the proper direction for the injection line to take is horizontal. In this type of card the point of top dead centre should not show a vertical line extending above the horizontal, or nearly so, injection line. If the extension rises above the height that a compression line would show, it means that there is slight preignition, and ths should be corrected. If the injection line starts out horizontally below the point of maximum compression, it means that the injection is too late, and this, too, should be corrected.

In cases where the load on the engine is subject to large and comparatively sudden changes, and where the ar injection pressure is set for the average load, either of the above-mentioned cards would result. It should be noted, then, that when taking cards the engine should be tuned up to the average-load conditions. It would be well in such cases to fit an automatic device for taking care of the changes in load. This would avoid the knocking that occurs when the engine suddenly runs "light." By the time the operator adjusted for this condition the load may have come on again. These varying conditions do not obtain in marine practice, as the load is constant. In marine cases where it is desired to run at half-speed, a favourite method is to "cut-out" half of the total number of cylinders, thus maintaining good working loads in the operating cylinders. The number of cylinders in a marine unit is such that the engine can be started up from any position of crank angle. In a two cycle engine four are enough; in a four-cycle engine six will be required.

Use of Starting Air

In a stationary plant it is not necessary to have all the cylinders fitted with starting valves. It will then be necessary to turn the engine over to a crank position, just past top dead centre, for the starting cylinder. In this way the cylinders not equipped for air-starting can start directly on fuel, and when they carry the load the starting cylinder or cylinders can be changed over to run on fuel. The air-starting valve and the fuel-control valve are so arranged that the two are never in operation at the same time. This must necessarily be so, as the high-pressure air in conjunction with the fuel would set up pressures far in excess of that normally allowed. In marine practice all the cylinders are fitted for starting. Here it is necessary to start all the cylinders on air, and then it is usual to change three over to fuel after the engine gets turning. As soon as these three take hold the three others are changed over to fuel. When the engine is in good running order the whole operation takes less time than it does to tell about it.

As little air should be used in starting as possible, so as to conserve the supply, and also because the expansion of the air will cool the cylinders. It is particularly necessary to conserve the air supply in marine practice where the engines are subject to manœuvring.

Racing

In some cases where speed control is obtained by action on the governor spring, the engine will race when the load on the engine is taken off and the engineer has to make a dash for the control to slow down the engine. This is caused by too few coils in the governor spring. A new spring with more coils should be used, the use of a short throw for the full control of speed should be abandoned, and a number of turns of the handwheel substituted. In the larger marine engines the only time there will be a tendency for the engine to race will be when the propeller comes out of the water. Since, otherwise, speed control can be obtained by cutting out some of the working cylinders, all that is necessary is a good overspeed governor. This will completely stop the fuel, except possibly to one cylinder, immediately the engine reaches a speed 10 per cent. greater than its rated speed. In the case of oil engines this governor action is instantaneous, as the fuel is stopped immediately by a small valve. The fuel that is still being supplied to the one cyinder will be sufficient to keep the engine turning over, so that when the load comes on again the other cylinders will be in condition to resume the load.—"Power Plant Engineering."

IMPROVEMENT IN DESIGN OF FRICTION CLUTCHES

(Continued from page 30)

ball bearings which represent the utmost efficiency in clutches of this design.

It is possible to use this clutch up to rim speeds of 5,000 ft. p. m. In these clutches and friction cut-off couplings the centrifugal force, which is a big factor as high speeds are involved, does not detrimentally affect the operating mechanism. We stop at rim speeds of 5,000 ft. p. m., but this permits many of the clutches to be used up to speeds of 1,750 r. p. m. and for this purpose they are used very generally by centrifugal pump manufacturers and other jobs where direct connection to high speed gasoline engines or electric motors is desirable.

The particular advantage to the manufacturer in making installations of clutches, is that each clutch replaces one countershaft, and the cross belt for every machine driven through a clutch. It also permits the cutting off of the power closer to the prime mover than with tight and loose pulleys. This saving in countershafts, in belts and in power with the decreased amount of equipment and reduction in light and noise is a great advantage.

Many manufacturers have the notion in their heads that the real up-to-date equipment is an electric motor drive for each machine. That is false doctrine as applied to light machinery and the ordinary small equipment. We have in mind an instance in Niagara Falls where a concern had 100 5 h. p. motors direct connected to buffing lathes. The average h. p. requirement for each machine was two h. p. At very infrequent intervals it might take four or five h. p., but the majority of the times the machines were driven by motors more than 50 per cent. of excess capacity.

The upkeep on the motors, the initial investment, the uneconomical power take-off from oversize motors made it altogether a very expensive outfit. On the other hand, they decided to sell those motors, put in 100 plate type clutches and by the use of approximately 10-20 h. p. motors they drove through group drives with Hilliard clutches ten buffing lathes with each 20-h. p. motor and had still plenty of power. It will readily be seen that this reduced the number of motors to 20, the connected load to 200 h. p., and a saving in connecting loads of 300 h. p., and so far as the investment goes, the cost of the necessary clutches and the 10 20-h. p. motors was far less than the installation cost and the initial cost of the 100 5-h. p. motors.

Another interesting installation which has been in for a period of more than ten years, is some 250 to 300 clutches driving punch presses in the plant of the Eastman Kodak Co. This does away with the tight and loose pulley proposition and they stagger the machines so that they have two lines of presses driven from one main line shaft on which are mounted plate clutches with driving pulleys, driving direct to the presses. They find it unnecessary to remove their belt when changing dies, due to the special clutch made for the purpose.

Drummondville, Que.—It is reported that tenders will be called by the Southern Canada Power Company early in the spring, on a hydro-electric development located on the St. Francis River, three miles from Drummondville.

Vancouver, B. C.—The British Columbia steel works project has been temporarily abandoned. Negotiations are still going forward, but the provincial government has decided to do nothing further with proposed legislation to aid the enterprise financially.

Safe Practice in Handling Acetylene Generators

Best Housing Methods Under Different Conditions—Fire Hazard Requires Special Attention—Natural and Artificial Lighting of Buildings—Pressure in Pipe Line Important

THERE is one of three things to do with the acetylene generator—it can be housed in a separate building away from other buildings; it can be housed in a lean-to building or shed adjoining your plant; or it can be installed inside one of your plant buildings. A separate isolated gas house is the ideal method, especially so if you go to the expense of having a substantial structure with floors at truck floor level, and divide the building into three or four compartments, using one section for housing the acetylene generator, one or two sections for the housing of calcium carbide and acetylene cylinders, and another section for the storage of oxygen cylinders. The isolated generator, carbide and gas storage warehouse need not necessarily be of fireproof construction, although such construction is preferable. In the case where it is decided to house the acetylene generator in a building which is a lean-to to your main plant, it should be separated from such plant building by an unpierced fire wall.

Where it is decided to house the generator inside one of the plant buildings, as said before, it is important to be sure that your insurance companies do not object, and also to see that you are not breaking some local ordinances. However, if such is not the case and you are housing the generator inside, a special compartment or room must be constructed, and such compartment be built of non-combustible materials. The door to such a compartment should preferably open to the outside, but if it does open into the main building or shop, the door should be of the fire, self-closing type. You will readily appreciate, however, that it is far more desirable to have the door open to the outside; then if there is any leak of gas there is no chance for the gas to escape through the door into the main building or shop, with the possibility of being ignited by some heat or spark-emitting device.

In the opinion of the writer the acetylene generators should not be installed inside buildings where the building is more than one story in height, except in the case of a special generator house provided with two floors, when the second floor is sometimes used for the storage of a supply of carbide and for charging the generator. Be sure to see that the generator stands on a substantial and firm foundation. We know of cases where generators were put up on a flimsy foundation, which were later undermined by the water discharged from the generator, and as a result, the generator canted over and broke off certain piping connections, causing serious trouble.

A generator room must be protected from freezing. This is most important. Freezing up of acetylene generators is the cause of fifty per cent of the accidents that have happened with them. One should never attempt to lower the freezing point of the water by using calcium chloride in an attempt to do away with the necessity of heating, for the reason that the calcium chloride not only tends to corrode the generator itself, but will gradually permeate the whole piping system and cause serious trouble.

The recommendations here set forth are made in the hope of serving the manufacturer and user of acetylene and help him to steer clear of accidents which need not occur. Remember that safe practice does not end with the proper operation of your welding equipment. Welding must only be used for work where welding can be considered good and safe practice for construction or repair. Some users become over-enthusiastic and attempt to employ welding on certain work where it should never be attempted and, consequently, fall down badly, with the result that it tends to give welding a bad name and creates a feeling of insecurity about the process in the minds of those who are considering its use.

Generator houses should be provided with plenty of daylight illumination, and plenty of head room. It must necessarily be well ventilated, and also be provided with good and sufficient artificial illumination. This must necessarily be of the incandescent electric type, with globes properly protected and with switches outside the building. Certain existing rules call for acetylene generators to be charged during daylight hours only, but such rules are to-day obsolete and cannot be complied with for the reason that many generators are in constant use, and during the winter months it is necessary to charge in other than daylight hours. For this reason it is essential that the artificial illumination be good.

One would think to-day that any workman who could get a job would be educated sufficiently to know that you can't bring a naked flame in contact with a combustible gas without getting ignition or explosion—yet a considerable percentage of the accidents that have occurred with acetylene generators have been caused by this very thing. For this reason it is strongly recommended that good natural and artificial illumination be provided in the generator house, so that there will be no possible inducement for the thoughtless workman to strike a match or use a lantern when examining the generator. The instructions furnished by the manufacturers of acetylene generators for the installation of their machines should be followed closely, and it is advisable, when at all possible, to have the manufacturer install the machine and put it in operation.

It is quite unnecessary to say anything about the installation of acetylene gas piping, beyond stating that it should be of ample size to meet the estimated maximum demand and should be installed according to the requirements of the National Board of Underwriters. We venture to suggest that if any who have acetylene installations would secure a copy of the National Board of Fire Underwriters' rules, and would peruse these rules and observe whether the installations comply with them or not, quite a number would find that the National Fire Underwriters' rules were not followed when the installations were made. It should be appreciated that National Board rules are recommended and drawn up by the National Fire Protection Association, a body that has always made a point of consulting with the industry when preparing rules. Possibly it can be said that National Board rules are the rules recommended by the acetylene industry. You will find amongst the National Board installation rules, those calling for escape and relief pipes to be carried outside of buildings. Personal inspection has shown numerous installations where no attention was paid to this rule and safety devices, if they were called upon to operate, discharged their gas inside of the buildings. This was asking for trouble.

A considerable number of the acetylene generators in use to-day for supplying gas to shop piping systems deliver the gas to the piping system at pressures up to 15 lbs. per square inch. It is therefore necessary to have the piping systems tested after installation at a good deal higher pressure than is commonly employed for testing out city gas piping systems. Let us now deal with the installation of the oxygen supply.

In the majority of cases, oxygen is used direct from a standard oxygen cylinder, a separate cylinder being used

---

As recommended by the National Safety Council.

use. In some instances, however, a number of oxygen cylinders are manifolded together, the gas being supplied to the shops through a system of piping. In rare cases oxygen is manufactured on the premises, the gas being first collected in a gas holder and then compressed in a receiver to a pressure of a few hundred pounds, after which it is passed through a regulator and supplied to the welding stations through a system of shop piping.

In those systems where it is desired to manifold a number of oxygen cylinders and supply gas to welding stations, it is extremely desirable that the necessary manifolds be purchased from a responsible apparatus manufacturer or be made up to their specifications. Every care possible must be taken with the installation of the oxygen piping system. It should be appreciated that oxygen, when supplied in cylinders, is under a pressure of approximately 2,000 pounds per square inch, and consequently oxygen manifolds must be sufficiently strong to withstand this pressure. It must be borne in mind also, that no combustible material should be employed in making up the manifolds, for the reason that oxygen under pressure is liable to cause a spontaneous combustion of such material.

When assembling the manifolds and the piping system, great care must be taken to see that fittings, etc., are handled with clean hands. Crease on a joint or in the interior of the piping might cause serious trouble. The interior of the piping must be clear of all scale and rust, and should be thoroughly washed out with caustic soda before being put into service. It is needless to talk about the actual setting up of welding apparatus, beyond saying that the manufacturer's instructions must be followed to the letter. In those installations where both gases, oxygen and acetylene are supplied from a single cylinder of each gas, the cylinders should be so located that they cannot be knocked over or struck by passing traffic. In most cases, where the individual cylinders are employed, it is the best practice to have both cylinders mounted on a truck, so that they can be conveniently transported from point to point.

Now a few words about the operation and manipulation of the generators and other equipment. When starting up an acetylene generator the first time, the instructions of the manufacturer must be followed in detail. Where possible it is extremely desirable that the acetylene generator manufacturer should not only install the machine, but should put it in operation. After the generator is charged with water and carbide, a connection should be made at the extreme end of the piping system, so that the gas can be discharged from that point to the open air. It is most important, before starting to use the gas for welding, to make sure that all air has been purged from the generator and the piping system. Some common sense has to be used to judge when this has been accomplished, but in the average installation, the decomposition of 10 to 15 pounds of carbide will have generated sufficient gas to expel all air from the generator and pipe lines. You may possibly wonder why this is so important, and we will therefore endeavor to explain more clearly.

Under normal and proper working conditions, the pressure of the acetylene gas in your pipe lines and generator will never exceed 15 pounds per square inch. Pure acetylene gas (that is, acetylene without any air mixture) at any pressure below 15 pounds per square inch is non-explosive. It is possible to fill any empty cylinder with pure acetylene at a pressure of 15 pounds per square inch, fit the cylinder with a spark plug and make a spark, and there will be absolutely no ignition of the acetylene, but if there is a small percentage of air present, there will be a violent explosion. If the same cylinder were filled with acetylene at 30 pounds pressure, and there was no air present and the spark plug was sparked, there would be a violent explosion. The action of acetylene under pressure between 15 and 30 pounds per square inch is somewhat uncertain, but all the best authorities have definitely decided that acetylene should never be used in a free state at a pressure in excess of 15 pounds per square inch.

Now, let us assume that you failed to purge your pipe lines of air or mixtures of air and acetylene, and were to light a blowpipe that is supplied with gas from the pipe line, and then suppose that the blowpipe backfired—it would be possible for the backfire to propagate right through the piping system up to the flashback or hydraulic seal, which is necessarily attached to the discharge outlet of all generators. This backfire along the piping system might be of sufficient violence to split the pipe or loosen the joints. Cases are known where, while the generator was being purged, a cap at the end of the piping system has been removed and a match applied, under the idea that as soon as the discharge from the pipe would ignite, it would show that all air had been driven out of the pipe. In such cases, of course, an accident has generally occurred, the mixture of gas and air discharging from the pipe having ignited, and owing to the orifice being large and the velocity of the gas and air comparatively low, ignition has propagated throughout the piping system.

Oshawa. — General Motors Corporation are making additions to their power plant. Goldie, McCulloch water tube boilers are being installed. Present plant includes two Leonard boilers with Detroit stokers, and two Inglis boilers, hand fed. The new installation will be equipped with Detroit stokers.

CONDENSITE CELERON IN THE RADIO INDUSTRY

WITH the development and expanding use of radio, condensite celoron and vulcanized fibre have found many new uses. Radio transmitting apparatus often demand very high voltages and currents which, at the high rate of vibration or, in other words, "frequency" developed, would soon destroy all but the best insulation. The essential electrical qualities of an insulator are that it shall have high volume and surface resistivity; high dielectric strength, and a low power loss or "phase angle." An explanation of the above terms condenses down to the fact that the insulation must be the best non-conductor of electricity that can be had. Condensite celoron is stated to possess certain mechanical properties that are especially adapted to radio service.

Radio voltages and currents are very much more destructive to insulation than equal voltages and currents used in commercial work. This is due, as stated above, to the high frequency involved. Where very high frequencies are used even the best insulation becomes a conductor of the current. In comparing the electrical qualities of an insulator, the surface and volume resistivity, dielectric strength and phase angle are all inter-related. If the material is of such a character that part of the current will tend to flow through it, or be absorbed by it, then a power loss develops measured by the phase angle, which is another way of expressing in degrees the percentage of power lost. Therefore the resistance which the material possesses to withstand these current leakages is expressed in terms of volume and surface resistivity. Another important property of the material is its dielectric strength or, in other words, the voltage required to puncture the insulation. This last-mentioned property is somewhat dependent upon the other three.

Probably the greatest use for this material in the radio industry is in the manufacture of panels. Possessing a beautiful finish, coupled with the fact that it can be readily machined in the way of being sawed, drilled, tapped or engraved, in addition to its excellent electrical properties, make it an ideal panel material. Its use runs from the simple crystal set to panels two to three feet square and up to one-half inch thick for the ultra-sensitive receiving set with its many stages of amplification. In the construction of the receiving set it finds additional uses in the form of tubes on which to wind the wire, end plates for the condensers, vacuum tube bases, rheostat bases, terminal blocks, etc. In transmitting equipment its insulating properties make it very serviceable for mountings of inductance coils, for high voltage condensers, spark discharges, transformer housings, switchboard panels, antenna switches, relay keys and many other relative applications.

Machines Tested by Sound

Testing Devices Where Detection, Location and Comparison of Sound Are Interpreted

C. E. NOEL STORR

FOR a long time there has been an effort to build testing devices that would make it possible to determine and, in particular, locate irregularities in operation of machinery by the sound emitted.

The author developed his initial apparatus in order to locate mechanical defects in a series of very large engines which did not run quite right. To do this he devised an instrument with two ear pieces and flexible connections to the reproducer. While the device was crude and far from efficient, the difficulty in the engines was traced with very little trouble and with perfect comfort. Later on another problem arose in connection with small gear boxes which contained a double-reduction spur gear mounted on ball bearings. Some of these boxes failed to pass inspection on the ground of excessive noise. A difficulty also arose on account of the irregularity of the rejections, since batches considered noisy by the test room would perfectly pass, while nominally silent batches failed to do so, due, of course, to the entire lack of any definite standard of reference for either the inspector or the works staff. It therefore became desirable to find a way of measuring the sound of the boxes.

The construction of instruments for the detection and location of sound is complicated by the fact that in connection with mechanical work there are two distinct purposes for which such instruments may be applied, namely the detection of internal or mechanical sound and external or atmospheric sound. For example, in examination of the running condition of the balls in a journal bearing the internal sound only is of interest and not any external noise the bearing may make. On the other hand, in many forms of construction it is desired to reduce the external noise to a minimum and it is quite possible that a test of the internal sound may lead in such cases to a totally incorrect conclusion.

To deal with the two different aspects of the matter there are two different types of reproducer. In the first place, there is the tectoscope, which is arranged with a test rod and reproduces only the internal sound of the bar with which the rod is in contact. The tectophone, on the other hand, is arranged with a conical mouth and reproduces the external sound when the mouthpiece is held close to any object.

It will be noted at once that one instrument serves to check the results obtained with the other. For example, the contact breaker of a magneto will show a considerable blow from the rocker arm when tested with the tectoscope, but except on a few very silent engines the blow will not be heard externally when tested with the tectophone. In other words, the first instrument will indicate that there is a distinct mechanical blow taking place, and the second test will show that in the matter of improving the general silence of operation this blow is of small moment.

The foregoing example serves to show that the clear reproduction of even minute internal noises should enable worn or faulty parts to be located quite easily, while it also brings forward the use of the second type of instrument for checking the amount of external noise arising from a given internal source. Thus parts which may give rise to external noises may be traced, although it is more than likely that in some cases the internal cause is of small magnitude.

There are other general applications of the tectophone; for example, there may be two universal joints on a common shaft, and either or both may be dry and noisy. In some cases of this nature the tectoscope applied to the nearest bearing on the shaft might fail to give a clear indication on account of the noise of the bearing, but if the tectophone is held quite close to each joint in turn the squeak can be instantly located. The above instance applies to many similar problems and includes the tracing of gas, compressed air, and similar leaks from pipes and plant in general, the flow of a liquid in the pipe being indicated quite distinctly by the tectoscope.

The author gives descriptions of ways to proceed in testing the operation of various parts of an automobile engine, selected here as an example, by means of his apparatus. Sounds picked up by this apparatus may be compared either with each other or with a standard which is to be taken as a fixed quantity. For general shop tests a pair of reproducers are used connected to the head frame. If, for example, the left-hand reproducer is placed in contact with No. 1 cylinder, the sound emanating therefrom will be the only sound audible to the operator. On placing the right-hand reproducer in contact with No. 3, however, the relative "slap" of the two cylinders can be instantly compared, this being preferable to an attempt to remember the relative intensity of No. 1 and making a mental comparison after testing No. 3.

It should also be noted that when required the method enables the internal sound to be compared with the external; and as in some forms of construction the section or shape of the casing may cause, say, four tappets and cams which are all of equal intensity internally to give very different external effects, the combined test should enable any confusion to be avoided as to the actual cause of the defect. In fact, it should be of considerable assistance in the industry for purposes as widely different as the choice of suitable material for the exhaust pipe and the design of a gear-box lid.

Other applications of the use of this apparatus are described, from which it would appear that by these means a considerable amount of information can be obtained at a small expense in time. For example, many sources of trouble in closed bodies can be easily obviated with the aid of the tectophone which will trace body squeaks, panel drumming, and the periodic drumming of wings and undershields under actual running conditions on the road.—Mechanical Engineering.

WHAT IS METAL FATIGUE?

With repeated stress as the basis of the explanation, the old theory of crystallisation of metal as the cause of fatigue failure is now abandoned, and we are taught to view failure as the outcome of the progressive spreading of minute cracks across the metal. This, of course, is not a complete explanation, for cracks are an effect, not a cause, and the phraseology which refers to repeated stress as the primary cause leaves the reader in a rather hazy condition concerning how and why the stress acts as it does. The search for exactitude in that direction may be of more interest to the scientist than it is to the average engineer, who need not go beyond the chain of effects in order to possess all the metallurgical knowledge that his work may demand. Questions of origin may be advanced towards solution by a use of the film. In the meantime some interesting tests are reported in connection with Illinois University, where the latest reversed-bending testing machine can be run at 1,800 revolutions per minute in producing cycles of completely reversed-bending stresses. Wrought ferrous metals appear to have a well-defined failure limit, accompanied by a rise in the temperature of the metal undergoing stress. Some difference between British and American figures relating to the endurance limit of cast iron and steel castings is disclosed, and further experiments have been arranged for the purpose of verification. One of the important facts recorded is that poor surface finish may lower the endurance limit by 18 per cent. Shape also influences the result. Such facts serve incidentally as reminders that machine designers, in many cases, fail to make adequate allowance for localised stress.

Building men in Ottawa anticipate something in the nature of a boom in that city this year. Permits last year reached the exceptional record of $5,021,782. Labor is abundant except for a few skilled lines.

Cause of Boiler Explosion

WE HAVE received a letter from a correspondent, which appears in another part of this issue, which was accompanied by a complete article taken from an American Engineering Paper relative to the explosion of a boiler of the locomotive type. Unfortunately the article is too long to publish, but our correspondent appears to thing that the report is at variance with the article appearing in the Dec. 20 issue of this paper. We are prone to think, however, that our correspondent has not interpreted our article on this subject correctly, otherwise be could not compare it with the case in the article he submits.

The Manchester Steam Users Association, as the majority of engineers know, is one of the greatest authorities on the operation and design of steam boilers in Great Britain, and C. E. Stromeyer their present chief engineer, is known the world over for his researches in boiler work and experiments on the ageing and fatigue of steels. Some years ago, however, it was thought necessary, on account of the divergent opinions upon boiler explosions, to conduct certain experiments to disprove that cold water sprayed upon a red-hot boiler plate, would cause an instant generation of steam sufficiently quick and so voluminous as to cause an explosion. We think it was generally accepted by the Board of Trade and all other engineering authorities, that the experiments conducted fully proved all they set out to prove and, therefore, it was finally accepted that explosions were not caused due to these conditions.

In reading over the extract from the articles submitted to us, we are informed "That there is no doubt at all, from the condition of the tubes, which are collapsed, and also from the condition of the crown sheet, that the disaster was caused by low water." The unfortunate part of the report, which no doubt has misled our correspondent is, that a few minutes prior to the explosion, the owner's son saw the engineer start the injector, but the report does not tell us that this caused the explosion. We are distinctly told in this report, that as a result of the investigation the cause of the explosion was fully revealed and that low water was responsible for the disaster, also that the crown sheet of the furnace was very badly burned. We think those last few words sums up the whole situation and allows us to place our finger upon the direct cause of the explosion. A boiler never explodes except due to weakness and here is the actual weakness. If the crystalline structure of a plate is destroyed due to being burnt, the strength is very materially affected and it is not at all unlikely, if that plate is in a boiler under pressure, that some form of disaster is sure to follow. In this case it did, and it is no use trying to associate the turning on of the injector with the explosion as the injector was turned on several minutes before the explosion happened. The furnace crown was burned and consequently very materially weakened. Since the shell of the boiler was intact and the explosion was due directly to the collapse of the fire-box, we see exactly what has happened and it is of little use trying to create a mystery around a situation like this, when an examination of the plates betrays the whole cause.

It was on account of this growing tendency to enshroud such mishaps with mystery, that we were prompted to publish this experiment, the main object being to disillusion those who unfortunately had come to regard such a theory as gospel, and, at the same time, to fortify all engineers against the acceptance of such a theory which must sooner or later be submitted to them.

Future of Water Turbines

IN ANOTHER part of this issue, we have dealt very briefly with the water turbine showing its application to one of the hydro electric units at Chippawa. This form of prime mover is a machine that is bound to claim very considerable attention in the future on account of the vast sources of undeveloped natural water supply we have at our disposal in this country. We are always aiming at cheaper power which must consequently resolve itself into larger and still larger power stations, getting rid of scattered and haphazard methods which have proved to be slow and costly. With a view to reducing the cost of power, the price of labor must be considered and with this in view, a special control stand is provided for each unit containing the necessary indicating instruments and control valves, so that a single operator can from one position, not only observe the performance of the turbine and all its auxiliaries, but can also start up, adjust the load, or shut down the turbine in the course of regular operation, or shut the turbine gates if required in case of emergency.

The manufacturer is, therefore, supplied with his power from a reliable source which is uninterrupted from transportation and coal strikes and which places him in that sphere where he is free from the anxieties and worries of fuel shortage.

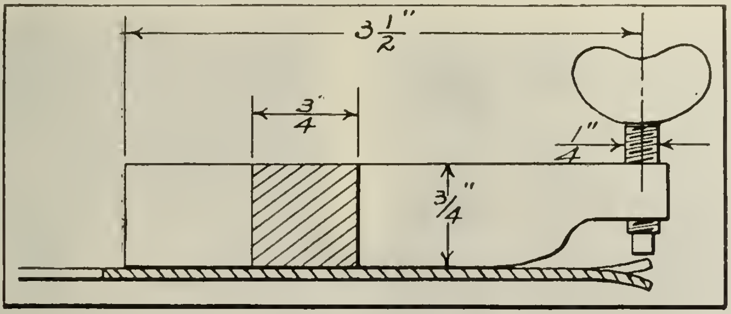
Operators' Point of View

GAUGE FOR SETTING BUZZ SAWS

By D. A. H.

Every mechanic knows that a saw must have set in it to cut freely. Saw factories set saws by machinery and there are machines used in wood working plants for the purpose; then there is the skilled man who sets saws with no other tools than a hammer and a taper block. But owing to differences in temper in different parts of the same saw as well as to blows of uneven intensities, hardly one saw in a thousand has all teeth set the same. Then, if there is one high tooth, the saw will never make a smooth cut; that tooth or a number of them will always be over-prominent and leave grooves in an otherwise smooth cut. The high tooth or teeth are almost impossible to find—they cannot be detected by eye or by laying a straightedge over the saw.

The sketch herewith shows a "tool" so simple that one wonders why it was not thought of before. It will pick out the high tooth instantly. When that has been lowered with a light blow, the gauge screw is turned a fraction and the next higher teeth can be spotted. In this way, the teeth that would positively cause scratching may be located and corrected before the saw goes on the mandrel. In construction, the gauge is a piece of ¾ in. square c. d. s. notched to let in the light and rounded a little way back to clear the tooth if its set extends back to the root. The screw is made a snug hand fit—snug so it will not jar out of its setting.



Gauge for setting teeth of buzz saw.

THE TREAT GAS PRODUCER

The chief distinctive features of this producer consist in a number of devices and power-actuated mechanisms which perform automatically various functions in relation to the fuel bed. Thus, a mechanism is provided for agitating the fuel bed and for feeding and distributing the fuel in the producer chamber. The machine to do this is located in the central circular opening of the producer top and is arranged to revolve bodily at a slow rate in a horizontal direction. The action for feeding and distributing the fuel and the agitation of the fuel bed functions in unison with the rotary movement.

The machine has a number of agitator bars extending vertically within the producer chamber so that the pair of agitator fingers of the lower ends penetrate the fuel bed. By turning adjusting screws the agitator bars may be raised and lowered at the will of the attendant. Fuel-feeding devices are provided. The blast is supplied through eight independently controlled steam-jet blowers of special design which are disposed uniformly around the outside of the producer. To each blower is connected an independt tuyere pipe which is arranged to extend through the tapering lower portion of the producer body, into the ash zone. The ashes are discharged through a water seal over the edge of the ashpan and a scraper device is employed which is designed to act against the interior surface of the ashpan.

Cleanliness is often underestimated in many factories. Superintendents, foremen and workmen should study this problem more to obtain the best results. Without cleanliness high class work is practically impossible, and it is the better class of work produced at reasonable cost that brings in and holds new customers.

Editor, Power House:

Please find attached an article and illustration from a recent issue of an American engineering journal which is quite at variance with your article appearing in "Power House" December 20th, 1922.

We would be pleased to hear what the Manchester Steam Users' Association has to say about this.

A. MURPHY,
Toronto.

Editor's Note:—

Mr. Murphy did not give us his address and we would ask him to kindly forward this to us in case we should wish to write to him personally upon this matter.

We cannot publish the whole of the article that was forwarded to us, on account of its length. The heading ran "Low Water and Removal of Fusible Plug Cause Boiler Explosion," and an extract reads:

"The 2-in. lever safety valve was found among the debris and was in good working condition and showed evidence of having been weighted to blow at 80 lb. There is no doubt at all, from the condition of the tubes which are collapsed and the condition of the crown sheet, that the disaster was caused by low water. This decision is further substantiated by testimony from witnesses who state that the 'engineer' was making an attempt to start the injector and the owner's son, who was also employed at the plant, made an effort to stop him but was unsuccessful. A few minutes later the boiler exploded."

POWER COMPANY HEAD GETS HANDSOME GIFT AT LEAVING

N. B. Ambler, superintendent of the Toronto Power Company at Niagara Falls for the past ten years, has resigned and leaves for New York. The employees of the power company presented Mr. Ambler with a handsome silver tea service suitably engraved. Mr. Stanley E. Thompson made the presentation and in a happy speech voiced the regrets of the employees in losing the genial superintendent. Mr. Ambler expressed his appreciation of the beautiful gift and thanked the employees for the splendid co-operation that he had enjoyed during his term of office. Mrs. Ambler received a huge boucuet of roses at her home.

Progress in New Equipment

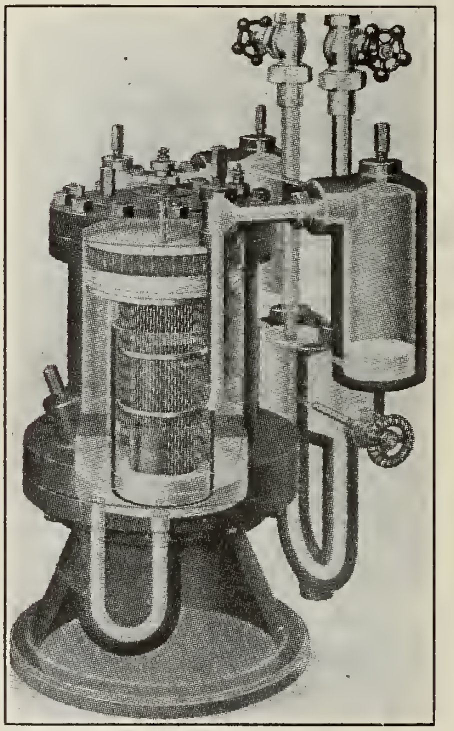
REPUBLIC FLOW METER

A phantom drawing of the meter body and seal assembly is shown on this page.

The two pipes terminating with globe valves are connected to the differential medium either a pitot tube or orifice disc by means of ⅜ in. piping. The dynamic or high pressure is admitted to the left-hand connection, when looking at the view of the meter in the drawing, and the static pressure of the right-hand connection. The dynamic connection leads to the mercury well, and the static connection to the annular space around the contact chamber.

When there is a flow in the line, the dynamic pressure becomes higher than the static. The mercury level is depressed in the mercury well and raised in the contact chamber in proportion to the impact of the flow. The rise and fall of the mercury in the contact chamber engages or disengages the successive ends of the overhanging rods, and thus adds or cuts out a given part of the resistances to which the rods are connected, regulating the amount of current flowing through the electric circuit. The resistances are so divided by the contact rods that the flow of the current in the circuit is directly proportional to the flow of fluid in the pipe. The electrical instruments, while measuring the current regulated by the flow, actually register the amount of fluid passing through the pipe.

Accordingly, the total amount of electrical energy measured by the flow integrator is the exact equivalent to the total amount of fluid passing through the pipe. The instantaneous flow of current shown by the indicator and recorder is equivalent to the instantaneous flow of fluid through the pipe. As the action of the meter depends only upon the level of the confined body of mercury, unrestricted by floats and mechanism, consequently, the slightest change in the flow of the fluid in the pipe will make an immediate change in the level of the mercury column, resulting in a corresponding immediate change in the reading of the electrical instruments.



Flow Meter.

PNEUMATIC RIVET CUTTER

A new type of pneumatically operated rivet cutter has been placed on the market recently. It has been constructed on the principle that a few intermittent heavy blows cause less vibration and therefore less distortion of steel plates than a number of comparatively light, rapid blows. The device consists of a dead handle for holding the machine, a throttle handle of crank design, taper throttle valve, a back head screwed onto the cylinder and secured by a locking device, a seamless steel tube cylinder with a cushion chamber in the rear end, a by-pass from back to front head, square coiled spring buffer, adjustable chisel lock, spade handle and chisel. The cutter is operated by moving the handle parallel to the cylinder. Both forward and return stroke is hand-controlled. Four blows, requiring about 15 sec., are said to be ample to cut off the head of a ¾-in. rivet. The device is made by the Chicago Pneumatic Tool Co., New York.

CHAIN SCREEN DOORS FOR FURNACE OPENINGS

Everyone who has had to work around ovens and furnaces knows what discomfort has to be endured by the operators from the heat and gases pouring out through the uncovered opening when the doors are thrown open and, further, what a chilling effect the cold air has upon the interior of the furnace and its contents. Doors, however, must be opened; be it to renew the charge, manipulate the contents, or study the interior conditions.

Many contrivances have been devised in connection with drop forge, steel, metal and chemical furnaces to avoid the adverse conditions arising from the opened furnace door, but these as a rule were solid, opaque and cumbersome. What was demanded was a door or shield which would permit a clear, unhampered view of the interior of the furnace or oven—would not in any way interfere with the free manipulation of the tools required to handle the charge, yet a door that would keep the heat in and the cold air out. In other words, a door was required which should possess at the same time the qualities of opaqueness, transparency and penetrability. These conditions have been met largely by the Wiegand Chain Screen Door.

Chain screen doors, in the form used mostly on steel, copper, glass and chemical furnaces, consist of a multitude of freely swinging individual strands of steel chain hanging close together from a steel bar in a manner to form a continuous sheet or curtain of chain, not unlike the familiar Japanese portiere.

This curtain of chain, hung before the uncovered opening to a furnace, and looking like a coat of mail, effectively hinders the heat, glare, gases and sparks from leaving the furnace and the cold air from entering. The loosely hanging strands of light chain with ease are parted and pressed aside by the tools or other objects projected into the furnace, only to fall together again and close the opening when entrance has been effected.

The preliminary plans have been drawn for the $7,000,000 power development at Rivieres des Prairies, Que., by the Back River Power Company.

Babcock & Wilcox Chain Grate Stoker

For Natural Draft

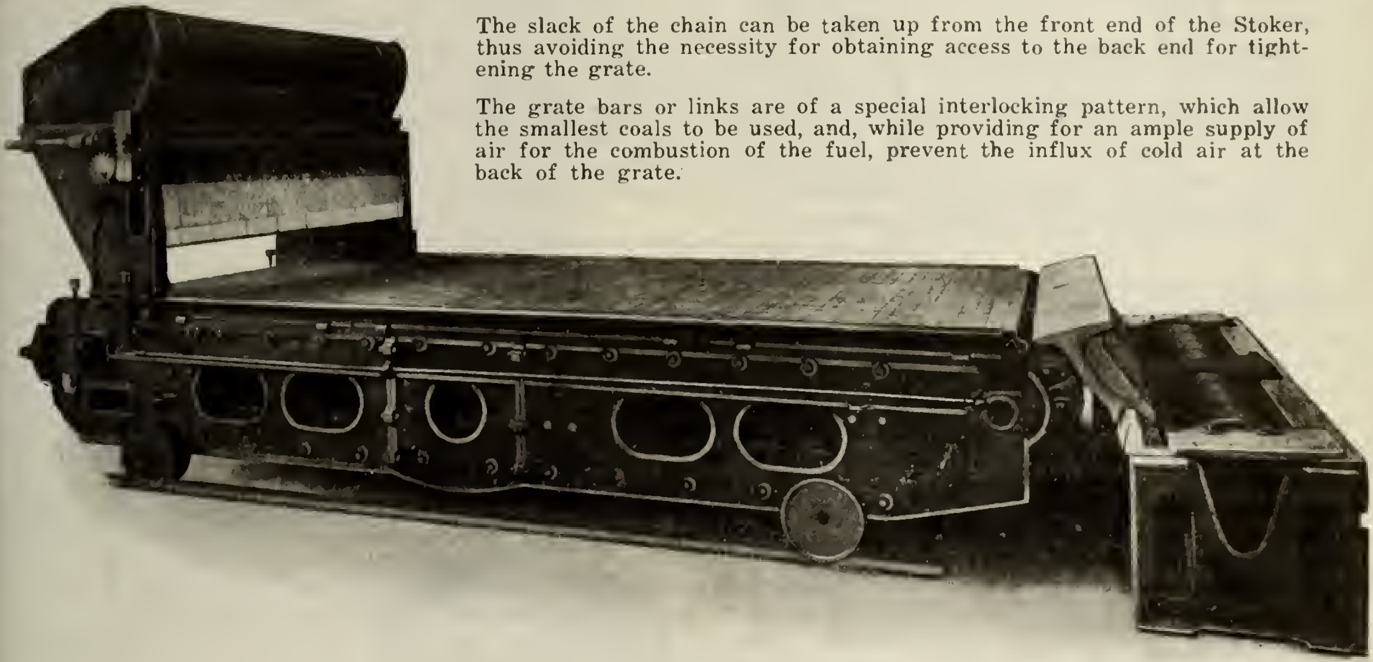
The grate consists of an endless chain of short interlocking cast-iron grate bars, linked together, running on angle irons and rollers and driven by a revolving shaft and sprocket wheels at the front end of the Stoker. The necessary power to drive the revolving drum is transmitted through a link chain and sprocket wheels from a shaft arranged either overhead or underground.

The starting or stopping of the Stoker, or the variation of speed, is effected through the B. & W. patent gear box, which can be driven at varying speeds. This box forms an oil bath in which the gear runs, and also contains an efficient clutch for putting the driving gear out of action should any unusual strain arise from an obstruction on the grate.

Any small repair, such as replacing a link, can be carried out with the Stoker in place under the boiler; but in case of need the whole Stoker can be brought out clear of the boiler, the frames being provided with wheels running on rails placed at the sides of the ashpit.

The slack of the chain can be taken up from the front end of the Stoker, thus avoiding the necessity for obtaining access to the back end for tightening the grate.

The grate bars or links are of a special interlocking pattern, which allow the smallest coals to be used, and, while providing for an ample supply of air for the combustion of the fuel, prevent the influx of cold air at the back of the grate.



The coal is fed over the whole width of the grate, and the depth of the fire is regulated by the adjustment of the vertically lifting fire door.

THE FEED OF THE COAL IS SLOW and the gas evolved from the fresh fuel as it drops on to the grate readily perfects its combustion by passing over the incandescent fuel further on.

The depth of the fire being regulated by a vertically lifting fire door, the Stoker CAN BE ADJUSTED IN A MOMENT to suit the class of fuel to be consumed and varying demands for steam, both by the depth of the fire and the speed of the grate.

The Stoker is easily manipulated and so simple that any fireman can understand it. It is the only form of stoker in which the undue admission of air at the back of the grate is prevented and with it THE HIGHEST EFFICIENCY is obtained.

The Stoker ultimately proves itself the embodiment of economy because it is efficient and saves coal over any other method of firing and the cost of upkeep is low compared with any other type.

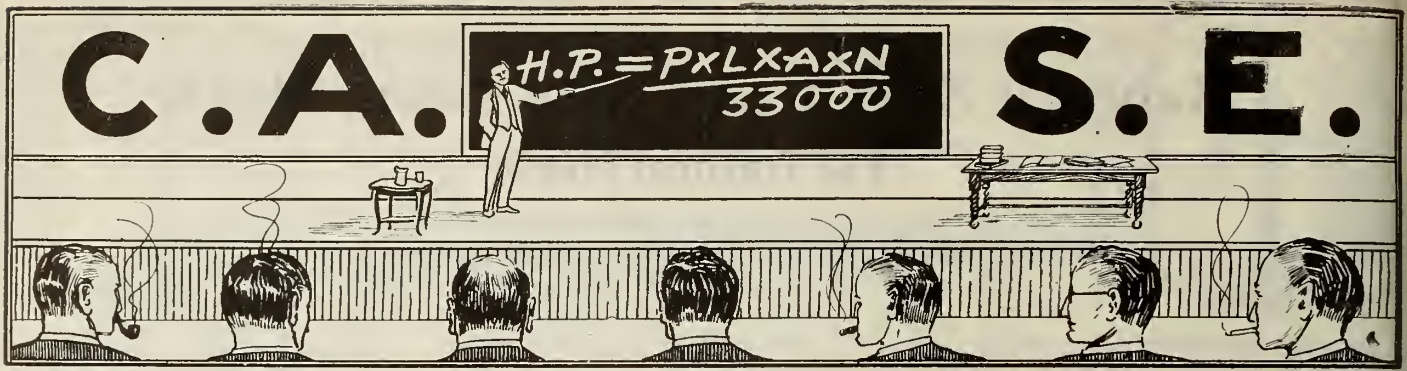
The first cost of some other makes may be less, but consideration must be given to whether they have the necessary metal in them to stand up under the work they are intended to do. By reducing the weight of metal the price can be lowered but only at the sacrifice of the durability, consequently the cost of repairs will be great. Due consideration should also be given to whether by any other method of firing the price of the Stoker can be recovered in the amount of coal saved in a given period.

Full information given on request.

BABCOCK & WILCOX, Limited

HEAD OFFICE FOR CANADA - COLLEGE ST. (ST. HENRY), MONTREAL

TORONTO OFFICE: BANK OF HAMILTON BUILDING



Toronto.—The 34th annual convention of the C. A. S. E. will be held in the Central Technical School on Lippencott St., Toronto, on June 25, 26, 27 and 28 this year. Judging by the amount of interest shown by the engineers and some of the supplymen, this convention promises to surpass anything previously held by the C. A. S. E.

Arrangements have already been made to secure the co-operation of the Canadian Manufacturers' Association, the Board of Trade and the Toronto Publicity Bureau.

Mr. Gordon Keith, of the Commercial Press, 51 Richmond St. W., Toronto, was elected general secretary of the joint committee.

At the joint executive meeting held January 30 at the residence of Mr. C. B. Turner, 894 Bathurst St., all the necessary arrangements were completed for the success of the convention.

Mr. R. McLaren, president of Toronto No. 1 C. A. S. E., is chairman of the joint committee and chairman of the convention committee.

The directory which Toronto No. 1 have had under way for some time will be ready for distribution before this issue goes to press.

Nearly all of the manufacturers of power plant equipment have representation or membership in the Supplymen's Association.

Officers ,of Exhibitors' Association

Past president—Grant E. Cole, G. E. Cole Co., 21 River St., Toronto.

President—J. Thompson, Dearborn Chemical Co., 2454 Dundas West, Toronto.

1st vice-president—H. G. Fletcher, Garlock Packing Co. Ltd., Continental Life Bldg., Toronto.

2nd vice-president — Earl Gordon, Thompson-Gordon Co., Ltd., Hamilton.

Secretary—Gordon C. Keith, The Canadian Manufacturer, 51 Wellington St. W., Toronto.

Assistant secretary—Geo. W. Wilkinson, Quaker City Rubber Co., Rochester.

Treasurer—Lloyd M. Archibald, Dart Union Co. Ltd., 93 Niagara St., Toronto.

Exhibition committee—C. B. Turner (chairman), 894 Bathurst St., Toronto.

Entertainment committee — E. F. Hetherington (chairman), Goldie & McCulloch Co. Ltd., Galt.

Reception committee—H. H. Gee (chairman), Jenkins Bros., Ltd., 48 Colborne St., Toronto.

Next exhibition will be held at Toronto, June 25, 26, 27 and 28, 1923.

Kitchener.—Lodge No. 9, C.A.S.E., at their last regular meeting on January 12th, had their annual installation, when Past President Bro. F. Pflug installed the following officers for the present year:—President, Bro. Chas. Merreth; vice-president, Bro. E. Klein; rec. sec., Bro. Con. Ott; fin. sec. and treas., Bro. C. Emmrich; conductor, Bro. J. Luft; door keeper, Bro. J. Ransch.

There was a fairly good attendance of members.

Considerable work upon educational matters will be effected during the year.

A stereopticon lantern has been bought which will considerably help in promoting greater interest with the engineers at their meetings. The Kitchener lodge intends holding an at home in the very near future and a very strong committee was appointed at the last meeting to insure its success.

POWER COMPANY HEAD GETS HANDSOME GIFT AT LEAVING

N. B. Ambler, who has been superintendent of the Toronto Power Company, Niagara Falls, Ont., for the past two years, has resigned and leaves for New York. The employes of the power company presented Mr. Ambler with a handsome silver tea service suitably engraved. Mr. Stanley E. Thompson made the presentation and in a happy speech voiced the regrets of the employes in losing the genial superintendent. Mr. Ambler expressed his appreciation of the beautiful gift and thanked the employes for the splendid co-operation that he had enjoyed during his term of office. Mrs. Ambler received a huge bouquet of roses at her home.

Dales Conservatories, Brampton, Ont. will erect 5 new greenhouses in spring approximately 40 x 400 ft. each. This will necessitate the erection of 2 new 200 H. P. boilers for heating them. A tunnel 600 ft. long will be made of concrete extending from power plant to the new houses. The total transaction will approx. $100,000. They have at present 4 Murphy Stokers with Inglis boilers.

IS SIR ROBERT HORNE CLOSING BALDWIN DEAL?

Sir Robert Horne's visit to Toronto has revived speculative interest in the future of Baldwin's Canadian Steel Corporation plant in Ashbridge's Bay, Toronto.

Sir Robert, formerly Chancellor of the Exchequer, is vice-chairman of the English Baldwins, parent of the Canadian concern. While no confirmation is available, it is understood that, since his arrival in America, some progress has been made in negotiations looking to disposal of the plant here to Bethlehem Steel Co.

The plant closed down early last fall as the result, it was stated at the time, of difficulties growing out of the coal rail strikes in United States. Materials were held up to such an extent that the plant could not be operated on a profitable basis. Another problem, which had been partly solved, had to do with the development of a working force. Production of tinplate in Canada was a new industry, for which there was no class of experienced help available. Labor of all kinds was high and the wage proposition was a very large item in an industry operating on a somewhat competitive basis. Nevertheless, it was felt that Canada offered a positive market for products of the plant.

It is understood that the Bethlehem Steel Co. are desirous of securing a plant in Canada that would serve as an adequate link in the chain of plants that they have been organizing to better serve their marketing purposes.

At the Baldwin plant it was stated that, as yet, nothing was available for publication. Capt. Hugh E. Poynter, president, is in New York.

Fuel authorities report that instances are known in which manufactuers have had to curtail, if not suspend, operations, owing to shortage of coal. This, it is claimed, is the result of failure to take advice offered some weeks ago to lay in stocks of coal while there was a limited quantity available. A temporary embargo went into effect subsequently and supplies have reached low levels. Coke which is now selling at from $9 to $10, could have been purchased two months ago at $7.70, at which price demand was inclined to hesitate, in anticipation of better prices. These, however, have not materialized.

Tested Efficiency and Tested Strength

—*proof that this insulation saves more heat*

A LENGTH of pipe insulation can save more heat in two ways: by its greater efficiency, and by its greater strength which increases its working life.

The greater efficiency of Asbesto-Sponge Felted Insulation has been proved by frequent tests—In a test of 26 insulations at the University of Wisconsin, it showed the highest efficiency.

The greater strength of Asbesto-Sponge is obvious—hit it with a hammer or test it in any way you please. It has lasted well over twenty years on hard service—a record that will be exceeded as the passage of time permits.

These tests prove the ability of Asbesto-Sponge Felted Insulation to save more heat in *both* of the ways such saving is possible—higher efficiency and longer life. Naturally, it is more economical.

You can hit Asbesto-Sponge Felted Insulation with a hammer—a test that has an important bearing on the life of an insulation in service.

EXPERIMENTS ON ICE MAKING

DESCRIPTION of what appears to be a novel method of ice manufacture in which an attempt it made to make a practically continuous cake of ice from which pieces may be cut off as desired. The method is based on the use of supercooled water. It is known that strongly agitated water may be cooled below its theoretical freezing temperature without solidifying. In tests made by the author, water strongly agitated and surrounded by a 14-deg. fahr. brine was reduced to 26.8 deg. fahr. before it flashed and ice crystals were formed. In other experiments water was not agitated but covered with a film of oil and a temperature of 25 deg. fahr. was reached without crystals forming. A piece of ice was dropped into the water and crystals slowly formed. The peculiar thing in the formation of these crystals is that they formed in laminated sheets. After proving that water could be supercooled, a plant was built with the idea in view that if ice crystals could be made in sufficient quantities and the ice cans filled with a concentrate of ice crystals and water at 32 deg. fahr., a marked step in the development of a more commercial method of manufacturing ice would be obtained. Notwithstanding all efforts made it was found impossible to use this plant on a commercial scale as the equipment would work only a few minutes, when the cooler would freeze up. This happened even when high back pressures from 42 up to 100 lb. per sq. in. were used. The apparatus, it seems, was provided with screens of 200 mesh in the bottom of the tank to prevent the crystals from being carried to the cooler. As a matter of fact, however, the crystal formations break up into such minute particles that they readily pass through eight to ten thicknesses of 200 mesh screen reinforced with cheesecloth, and these minute crystals once in the cooler cause the flashing.

A device was then developed for separating crystals by gravity. After the separator was connected between the tank and the cooler, supercooled water could be made and maintained for an indefinite period at temperatures below 32 deg. fahr., and it was believed that by introducing the supercooled water into a refrigerated can or receptacle the water coming in contact with the refrigerated surface would deposit lamination of ice thereon, thus removing the heat through water instead of through ice. Numerous experiments were made but without satisfactory results on a commercial scale at first. Thirty-seven forms of cans of various types and shapes were made. In all of these absolutely clear ice was made but in no case was it possible to deposit crystals that would adhere to the refrigerated surface or to the ice formed. This led to further experiments to determine the relation between supercooled water and ice crystals.

In the course of these experiments another means was employed in the hope of solving the problem. A large cast-steel ammonia-jacketed can, weighing 7,000 lb., was made in two sections, machined inside and bolted together. This can was 6 ft. 9 in. long and the ammonia-jacketed section 6 ft. long. It was open at the ends and the front end was provided with a cover and an inlet and outlet; in the center an agitator was provided. The idea was to admit supercooled water into the can through the top inlet, agitate it in the can, and discharge it from the lower outlet. The object of the agitator was to mix the supercooled water and crystals so that the entire mass would be of one temperature and the crystals would be deposited on the refrigerated surface of the can and thus make ice. Means were provided to lubricate the inner surface of the can, the intention being to make ice continuously, allow it to slide out of the can as made, and then saw it off into standard lengths. The system was not a success.

Experiments are now being conducted in an attempt to make ice in an open tank, separate the crystals in the water by a centrifugal separator and then press them into a cake by means of hydraulic pressure. The crystals made from supercooled water are so minute that they can hardly be distinguished from water when in a glass, being so clear. By subjecting them to pressure, however, they can be compacted so that solid ice can be made.

In the course of these tests an endeavor was made to stabilize the crystallization point by catalytic action. Various acids and alkalies were added to the water with a view of decreasing the freezing point and with the hope of discovering some means whereby the crystal formation would be retarded. Certain dyes were used, as well as starch, glycerine, and other chemicals. A thorough study of the crystal formation of sugar, salt, glycerine, and various chemicals was made and a number of very interesting experiments were conducted with electrical apparatus. Glass containers were made surrounded by coils of wire through which both alternating and direct current were applied with a view to stimulating or directing crystallization by magnetic lines of force.

It would appear, therefore, that while no commercial result has yet been obtained from the work of the writer, some facts of considerable scientific interest have been established.—Refrigerating Engineering.

The Eureka Planter Co., Woodstock, Ont., will start work early in the spring for an addition to its foundry, in which a considerable amount of new equipment will be installed. H. C. Norry is vice-president.

RECOVERING FUEL FROM ASHES BY MAGNETIC SEPARATOR

The presence of coke and unburnt coal in ashes often constitutes a considerable loss of fuel, and up to the present there has been no very effective method of recovering the combustible matter from the refuse. We are informed that Messrs. Fried Krupp, in Germany, have devised a magnetic separator for the purpose and that many of such machines are now in successful use. Practically all coals contain iron in the form of pyrites, which has no magnetic properties. The burning of the coal, however, converts the pyrites into oxides which are magnetic, and as the whole of the iron passes away with the slag the metal exists there in a very much more concentrated form than in the original coal. These facts are taken advantage of to effect the separation. The machine employed consists essentially of a magnetic drum over which the furnace refuse is passed. The drum rotates slowly about a horizontal axis, just as in the case of an ordinary magnetic separator. The ashes to be treated are delivered by a bucket elevator to a vibrating screen which separates them into various sizes. Each size is passed separately on to the circumference of the drum. The slags containing iron are held magnetically to the surface for a portion of the revolution, and then drop off into small wagons or other receptacles as the current exciting the portion of the drum which held them, is automatically broken. The coal and coke which may be present do not adhere to the drum, but leave its surface directly after contact with it, and fall into their own receptacles. It is said that lumps of slag up to 3-in. mesh will adhere to the drum and thus be eliminated from the fuel.

The magnetic separators are built in sizes capable of dealing with quantities of ashes ranging from ½ ton to 2 tons per hour. The fuel recovered by these machines can either be burnt under boilers by means of forced draught or it can be briquetted, both methods being in use. We are informed that about 90 magnetic ash separators are now in use in Europe and elsewhere, and that 50 more are on order. Among the users may be mentioned the Hungarian State Railways, who treat locomotive ashes by the method described. The agent is Mr. W. Stamm, 63 Queen Victoria-street, London, E. C. 4.—Engineering.

Cobalt:—H. H. Sutherland, promoter of the Great Northern Power prospect at Indian Chutes, said they fully expected to be putting on extra 8,000 horse power into Porcupine by July next, and furthermore, if the Hollinger wants it, they might increase this to 12,000 or 14,000 H. P.

"SAFETY" PLASTIC METALLIC PACKING

This packing is made of an alloy of the FINEST ANTI-FRICTION METALS combined with the BEST LUBRICATING MATERIALS, which always remain in the packing, making it practically Self-Lubricating and Frictionless. It is

GUARANTEED TO LAST THREE YEARS WITHOUT RENEWAL

In fact there are many Engines, Pumps, Compressors, Expansion Joints, Valves, etc., on which this packing has been in use for over 12 years with the very best satisfaction.

Let us send you further particulars also about our "Safety" Superheat Sheet Packing.

AGAIN TESTING COPPER TUBES

The use of copper for locomotive firebox plate and boiler tubes in the United States was abandoned many years ago, but the metal is likely to be tested again to determine whether it is cheaper than steel under present conditions. Copper is cheaper than it was in 1914, whereas steel is 50 per cent. dearer. One of the circumstances which caused the American railroads to discard copper was the high cost of the material, but the scrap value recovers a great deal of the original cost. In a paper by Mr. P. C. Dewhurst (Jamaica Government Railways) the author states that he does not see sufficient justification for the use of copper tubes unless it is on account of better conductivity. Owing to the high co-efficient of expansion of copper the tube sheets are distorted more between the cold and working temperatures than when steel tubes are used. Moreover, Mr. Dewhurst argues that steel tubes do not suffer from eroding at the fire-box end, just inside the tube sheet.

Cobalt.—Canadian Associated Goldfields will start operations, as soon as the winter breaks, on completing the development of its Windego Falls power scheme on the Blanche River, south of the Kirkland field. A preliminary development of 2,500 horsepower will be ready this summer, this amount of energy being available without damming. By building a dam and otherwise providing storage, this power position is stated to be good for 6,000 horsepower. The preliminary development will provide more power for the Associated Company's own operations, Crown Reserve, Argonaut and other possible users in the eastern end of the Kirkland Lake field. The company has had several requests for power from small developers. It has also been asked to consider transmitting power, from its Raven Falls plant, to new gold properties in Quebec.

OXIDIZED KEROSENES AS FUELS

The solution of still another industrial problem has been undertaken at the research laboratories of Carnegie Institute of Technology, Pittsburgh, in experiments to determine the relative efficiency of kerosenes and oxidized kerosenes as fuels.

In accordance with the policy of the Institute to link up its educational facilities with modern industry, the department of chemical engineering has been conducting a series of tests to determine the relative merits of various oils as usable fuels. The completion of this important work should go a long way toward solving the problem of oil conservation, by the possible development of a new fuel.

According to a report by Dr. J. H. James, head of the department conducting the experiments, oxidized kerosenes cause less "knocking" tendencies than straight kerosene when used in a kerosene engine. The tests also showed that oxidized kerosenes have approximately the same power development as ordinary kerosene, in spite of the fact that their thermal value is one-eighth less. Dr. James attributes the efficiency of the oxidized kerosenes to the better "clean up" in the combustion of these partially oxidized fuels.

The success of the experimental work at Carnegie at this stage gives promise that oxidized kerosene, which is manufactured by catalytic oxidation from low grade petroleum, may become a useful fuel in the future. Its properties may cause it to be used industrially in kerosene engines or blended with gasoline for use in gasoline engines. Although it has a somewhat lower fuel value than ordinary kerosene, one of the most favorable features of its effectiveness is that it undergoes much better combustion in the internal combustion engine.

The town of Kincardine, Ont., will install an auxiliary gasoline waterworks pump to cost $7,000. J. H. Scougall is clerk.

THE WEAR OF STEELS

Several tests have been conducted to determine the resistance to wear of hardened and tempered chromium steels. It was noticed that while the so-called standard hardened specimen, which was run on the upper shaft of the testing apparatus, invariably had a polished surface at the conclusion of every test, the bottom specimen, especially the tempered specimens, presented a dull appearance which was presumed to be caused by abraded particles sticking to the specimen. It seemed, therefore, that specimens with this dull mottled appearance would show a loss of weight less than the actual loss. To prove this several tests were made of Ketos steel running the standard hardened specimen on the lower shaft and the tempered specimen on the upper shaft. The curve of rate of wear versus tempering temperature obtained was similar to the previous curve but showed a greater rate of wear. The tempered specimens under the last-named conditions were free from abraded material at the end of the tests. Efforts will be made to prevent the adherence of the abraded metal particles to the specimen.

It is reported that the Back River Power Co., Riviere Des Prairies, Que., is having plans prepared for power development to cost $7,000,000.

Construction has been started on the foundation for the Belleview Pumping Station, Brantford, Ont., and bids for equipment will be received by F. Adams, engineer, March 1.

F. I. Fox, manager Ford Motor Co., of Canada, Toronto, is receiving tenders for the erection of a plant on Danforth Avenue, Toronto, between Luttrell and Victoria Park Avenues, at a cost approximately $1,500,000. The plant will cover an area of 15½ acres and is expected to be completed and in operation by next summer.

Bearing Metal
plus Service

Ordinary bearing metals may look quite similar to Magnolia Metal, weigh the same, and cost even a trifle less. But when you buy Magnolia Metal, you get the assurance of long and efficient service as well as just so much metal. U.S. and other government tests have proven Magnolia Metal to have the lowest frictional coefficient of any known bearing metal and to have every other requirement for its purpose besides. Magnolia Metal melts and pours well, is easily peened and scraped in, and is always uniform in composition. It is perfectly adapted to a wide range of speeds and pressures, quickly adapts itself to inequalities in the shaft and embeds the grit that might score the shaft or increase friction. Try Magnolia Metal on one of your bearings and test its superiority to your own satisfaction. 19

Less Work — More Wear

THIS plastic furnace lining, in unbaked form, is pounded into place by anyone who can use a mallet. When vitrified, it forms a jointless, air-tight, gas-tight lining that resists temperatures to 3,100 deg. F. and that outlasts ordinary fire brick two to four times.

Plibrico is delivered only in steel containers of distinctive appearance as shown below. Warehouse stocks in principal cities. Write to the Jointless Fire Brick Co., 1142 Clay Street, for your copy of the free fifty-page booklet shown above.

DISTRIBUTORS: Beveridge Supply Co., Ltd., Montreal; Shell Bar Boico Supply Co., Ltd., Toronto; Evans, Coleman and Evans, Vancouver, B. C.; Winnipeg Supply and Fuel Co., Winnipeg; Gorman's Ltd., Calgary, Alta.

A Striking Message

A STRIKING message to manufacturers of power-house equipment is derived from a letter written by a "Power House" reader in reply to a request for a criticism of the paper and for suggestions as to how it could be improved. Here is the letter:

"I believe Power House compares favorably with other power-house journals in many respects. One department I would like to see at least three times its present size is the selling section. Many of the ads. are from all-American U.S. firms but there must be many others, some of them with Canadian branches and agencies, who do not carry an advertisement in Power House. This is a mistake on their part, but for all I know to the contrary it may be due to the lack of energy on the part of the Power House ad. manager in getting after them. It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages so much as on the ADVERTISEMENT PAGES."

HINTS TO BUYERS

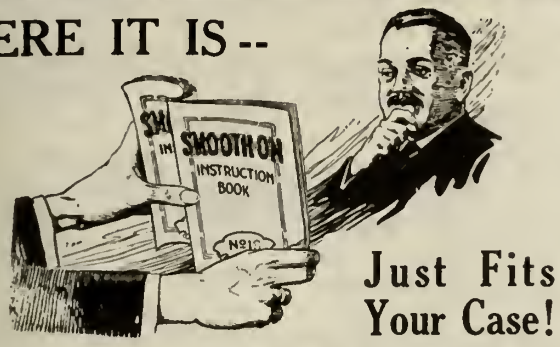
HERE IT IS--



Just Fits Your Case!

Many engineers have learned from experience not to say, "That will have to come down for repairs," until after they have tried Smooth-On Cements. For Smooth-On saves dismantling in a large proportion of cases.

SMOOTH-ON
Instruction Book No. 19

just off the press, contains 144 pages of engineering information and shows many instances of how time and money were saved by engineers through the use of Smooth-On Cements for making power plant repairs. This book shows you "how it is done"—quickly and economically—without dismantling machinery or pipe lines. Write today for your copy—IT'S FREE.

Smooth-On Cements are sold in 5-lb., 10-lb., and 25-lb., tins; also in larger sizes.

This ANDERSON Steam Trap

Positively
Prevents
Wasted
Steam

Use it on any Line

Wherever there is condensation the Anderson Model "D" Trap will give you economical service. Because it absolutely prevents loss of steam some odd thousands of users are "strong" for this trap. It is the most effective trap because it automatically adjusts itself to any pressure within its capacity. Valves are built of wear-proof, rust-resisting materials. Equipped with a removable strainer which prevents scale, packing, etc., from entering the valve.

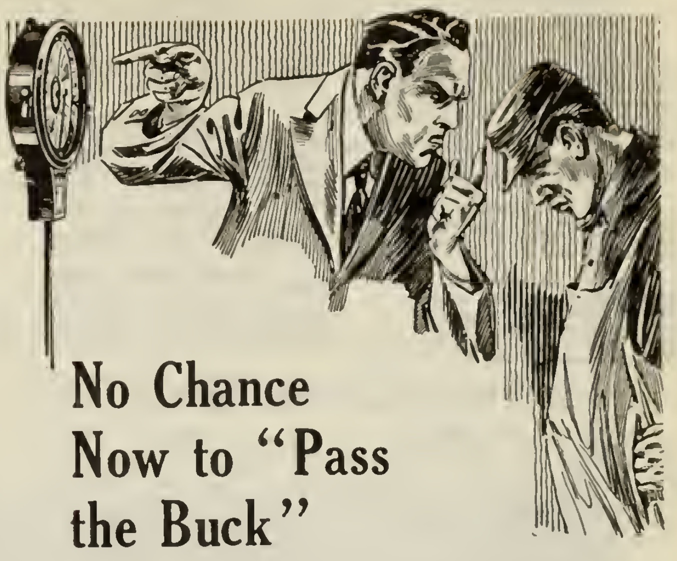
1935 West 96th St., Cleveland, Ohio.



No Chance Now to "Pass the Buck"

You can now place the blame on the exact man who makes the mistake when goods are ruined or other damage occurs as a result of not maintaining correct temperature. For, by installing a Columbia Recording Thermometer with the new **Time Punch** attachment, you have an automatic watchman that not only unerringly points out any carelessness or neglect, but also **pins down the responsibility and leaves no loophole for alibis or excuses.**

The chart gives a continuous day-and-night record of the temperature itself. But that alone isn't enough—you also want to know whether the temperature has been regularly inspected and undue variations promptly and properly corrected. And this the Time Punch attachment tells you when you use

Columbia Recording Thermometers
With Time Punch

The operator simply pushes a button when making each inspection, and the exact time of the inspection is immediately recorded on the edge of the dial, while the temperature chart shows the temperature at that particular minute. Thus, you get the whole story in an indisputable form.

If the operator fails to make an inspection at proper intervals, then the failure is shown by a blank.

Columbia Recording Thermometers (also Recording Gauges and Tachometers) with the new Time Punch attachment cost no more than an ordinary recorder alone—you get an extra check on temperature control at no extra cost. And it's a check that works both ways — the conscientious operator will take pride in having the record of his faithfulness always in evidence, while the careless or lazy operator will immediately brace up and try to avoid a bad record.

Catalog H-33 gives full information.

De Laval Oil Purifiers

are maintaining the efficiency of lubricating oil and the dielectric strength of transformer oil in power plants—large and small—throughout the United States and Canada. They effect instantaneous removal of water and sludge from used oil by means of centrifugal force. They occupy small space and require but little attention.

Write for Bulletin No. 105, which gives detailed information.

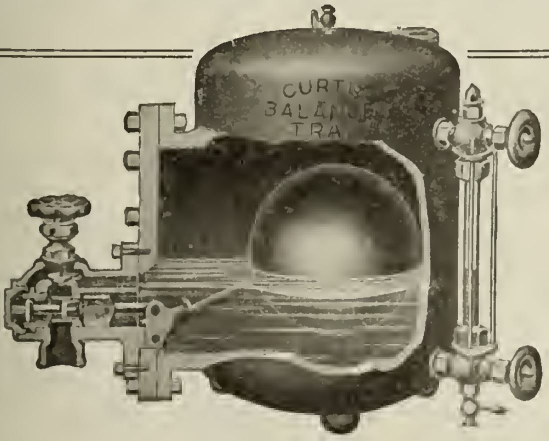
Curtis Engineering Specialties



Five Superior Features of the Curtis Trap

1. A perfectly balanced valve.
2. An absolutely frictionless valve.
3. The valve can be removed without breaking a joint, starting a gasket, or taking out a bolt.
4. The valve being frictionless and balanced, the whole power of the float is available for opening and closing the valve.
5. Each trap will operate perfectly on high and low pressures.

Write for our No. 50 Catalog of Curtis Engineering Specialties.

PLASTIC FIRE BRICK

ELIMINATE LOOSE BRICK
and FALLEN ARCHES

by using BETSON PLASTIC FIRE BRICK for repairs and for building complete, seamless, monolithic furnace linings, including front and rear arches, side walls, bridge walls and baffles.
No more fallen arches—no more in-leakage of cold air. But more power with less expense.
Shipped either mixed ready for use or dry to mix with water (the cost is the same) from warehouse stock in principal cities.

Write for valuable booklet.

When Answering Advertisements Mention
POWER HOUSE

FOR SALE

BURNHAM STEAM PRESSURE PUMP, 10 IN. x 1⅛-inch. x 12 in., nearly new, with Fisher governor attached. W. Ahearn, 538 McLaren St., Ottawa. When answering this advertisement please mention this paper. P.F.H.

I. H.C. 12 H.P. GAS ENGINE FOR SALE—ALL in good running shape, with 33-inch clutch pulley; will be sold reasonable on easy terms. Apply W. Harrison & Son, R. R. No. 5, Guelph. When answering this advertisement, please mention this paper. P.F.H.

ABSOLUTE BELTING BARGAINS—BELTING every description; rubber hose, thresher supplies, tank pumps, pump leather feeds, canvas. McGill auto powers, special reduced prices; for quality and price, you can't beat us. N. Smith, 134 Adelaide west, corner of York, Toronto. When answering this advertisement, please mention this paper. P.F.H.

TAYLOR SAFES FOR SALE—RARE OPPORTUNITY to secure a safe at small cost. They are in splendid condition. Inside dimensions and prices are as follows: 15" deep, 2 ft. 6" wide, 3 ft. 11½" high, fitted with built-in compartment. Price $250.00. 18" deep, 2 ft. 8" wide, 4 ft. 5" high, fitted with steel compartment. Price $200.00. Apply Box 10, POWER HOUSE.

SITUATION VACANT

SALESMAN WANTED FOR STEAM SPECIALTIES, power house and heating equipment; State age, education received, and previous experience if any. Box 101, Power House.

FOR SALE
Fuel Oil Storage Tank
10,000 GALS. CAPACITY
This is a new tank. We have not yet taken delivery of it, and offer it at a very attractive price.
MR. VOGAN, The MacLean Publishing Co., Ltd, 143 University Ave., TORONTO.

"Power House" Guide To Buyers
PAGES 46 - 54

Every Engineer, Mechanic and Electrical Worker will welcome this new master set. It will answer your problems.

It will help you with your daily work.—A sure source of advancement and higher pay. Complete up-to-date information that is thoroughly and easily explained on every branch of modern engineering and electrical practice.

AUDEL'S ENGINEERS & MECHANICS GUIDES
4750 PAGES $1 A MONTH
8754 ILLUSTRATIONS $12 COMPLETE
These Guides tell you all about—

Theory, Practice and Operation of ALL Steam Engines; UNIFLOW and POPPET VALVE ENGINES, and LOCOMOBILES. Locomotive-Marine Engines; Turbines; Rotary Engines --the Indicator--Lubrication--PRACTICAL MANAGEMENT. GAS, GAS ENGINES--*Aeroplanes* and *Aviation*--HOW TO SELECT AN ENGINE. STEAM ENGINE rules and formulae. Steam Boilers; Heat-Combustion; Fuel and Flue Gas Analysis-C02 Recorders-Construction of all types of Boilers,--Mechanical Stockers--Oil Burners--Setting--Chimneys--Mechanical Draught--HOW TO SELECT A BOILER--BOILER DESIGN based on A.S.M.E. BOILER CODE--OPERATION FIRING. Pipes, Fittings--Heating and Ventilation--Refrigeration--Cooling Towers--Condensers--Distilling Apparatus--Elevators--Cranes--Ropes and Cables--Splicing--*Practical Electrical Engineering* as an aid for engineers and electricians in obtaining a license--ready reference index, covering entire field of Modern Electricity.

SHIPPED TO YOU FREE

Not a cent to pay until you see the books. No obligation to pay unless you are satisfied. Send coupon now--today and get this new master set for engineers. Pay only $1 a month.

SEND NO MONEY

THEO. AUDEL & CO.,

What Kind of Reading Matter Do You Like Best?

Henry Ford with one of his favorite business newspapers. He considers it part of his business to read them and moreover finds pleasure in doing so.—By courtesy of the North American Newspaper Alliance, New York.

An entertaining story of Henry Ford and of his personality has lately appeared in serial form in daily papers throughout Canada, the United States and Great Britain from the pen of the Rev. F. F. Marquis, D.D., a former pastor of Mr. Ford's. This has been generally regarded as the most intimate sketch of him and his habits that has appeared.

In one of the chapters the question of what Mr. Ford reads is discussed. He is, we are told, not an extensive reader, but there is one type of literature which he on no account neglects to read and that is his trade newspapers. In the illustration above we see him with one of his favorite business newspapers.

This is typical of the average business man of to-day—the man whose attention you are anxious to secure by your advertisements. Whatever else he may or may not read, he will not miss the paper which gives him all the news concerning his own business.

You can send your message to the leading business men in Canada by means of the following MacLean publications, all of which are members of the Audit Bureau of Circulations, the hall-mark of Quality Circulation. Information regarding rates, and fields covered, will be furnished on application to

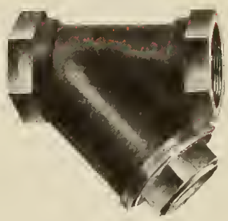
MORRISON

Strainers



For Use

on

All Pipe Lines

By preventing sediment, scale, or particles of foreign matter from passing into valves, regulators, cylinders, etc., Morrison Strainers constantly save considerable repair work, loss of time, annoyance and expensive shut-downs.

The construction is such that the flow is not obstructed through the strainer. All particles caught by the screen fall into the large chamber in the cap, out of the way of the flow. By unscrewing the cap all internal parts are removed, the screen can be lifted out of the cage which is cast solid with the cap and all parts easily cleaned and replaced.

Thousands of these strainers are in use, effecting a saving many times the installation.

A Time and Labor Saver—

JENKINS RAPID ACTION VALVE

Wherever an easily operated quick opening valve is desired there's a need for a Jenkins Rapid Action valve like that shown here.

This Jenkins model meets the need for a quick action valve that **can be opened instantly without water hammer**. This objectionable feature has been entirely eliminated through skilful designing and workmanship and because every valve is fitted with a Jenkins Renewable Composition Disc suitable for service required.

An ideal valve for Laundries, Creameries, Shower Baths, etc.

Write for full details of this time and labor saver.

"VICTOR"
Fig. 892

LUNKENHEIMER
Blow-off Valves

Remain tight in service, prevent waste through boiler blow-off lines, and thereby turn to a profit the losses caused by leakage, which frequently occurs at this point.

In Lunkenheimer Blow-off Valves the water is released gradually, due to the peculiar construction of the seat and disc. This virtually makes them safety devices, since they eliminate the dangers incident to undue agitation within the boiler or severe shock in the discharge line which result when Blow-off Valves are opened suddenly.

Lunkenheimer design and construction reduces wear to a minimum. When wear does appear the renewal of the parts affected is easily accomplished. The installation of Lunkenheimer Blow-off Valves is the solution of your boiler blow-off problem.

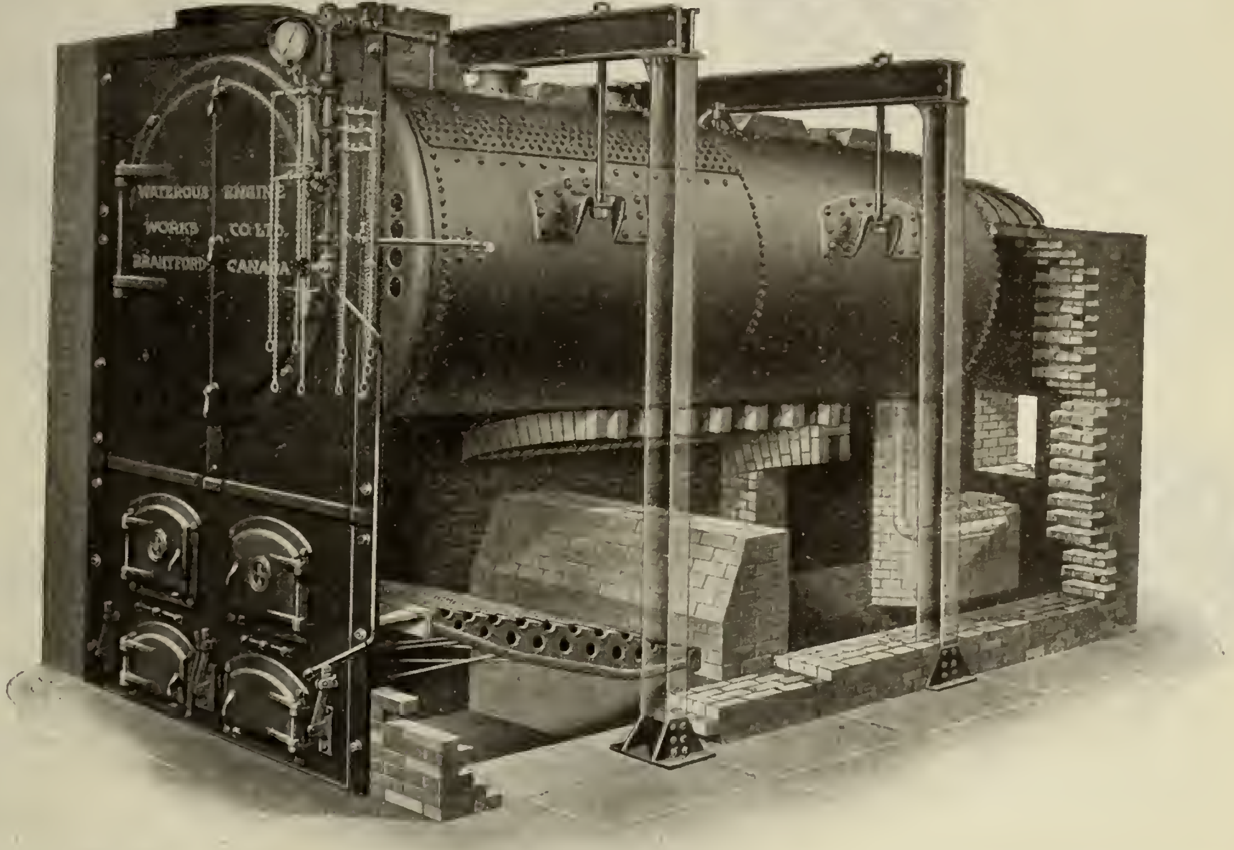
Files Stokers

Hand Operated



"Are Giving Absolute Satisfaction"—

S. KANN SONS COMPANY, Washington, D.C.

"In answer to your communication of Aug. 1st in reference to our **Files Stokers,** will state that they are giving **absolute satisfaction.** We have them installed under two 250 H. P. Heine Boilers.

"While we have not made a test of the actual saving in coal, would judge from 10 to 15% as our load increased 25%. We were able to carry steam without difficulty, which we could not do when our boilers were equipped with the down-draft furnaces.

"Our smoke laws in this city are very strict and with one or two exceptions we have always been able to comply with same. With careful firing there should be very little smoke. Our expense for upkeep has been very reasonable.

"Hoping this information is what you desire, we remain,

"Yours very truly,

"THE S. KANN SONS COMPANY."

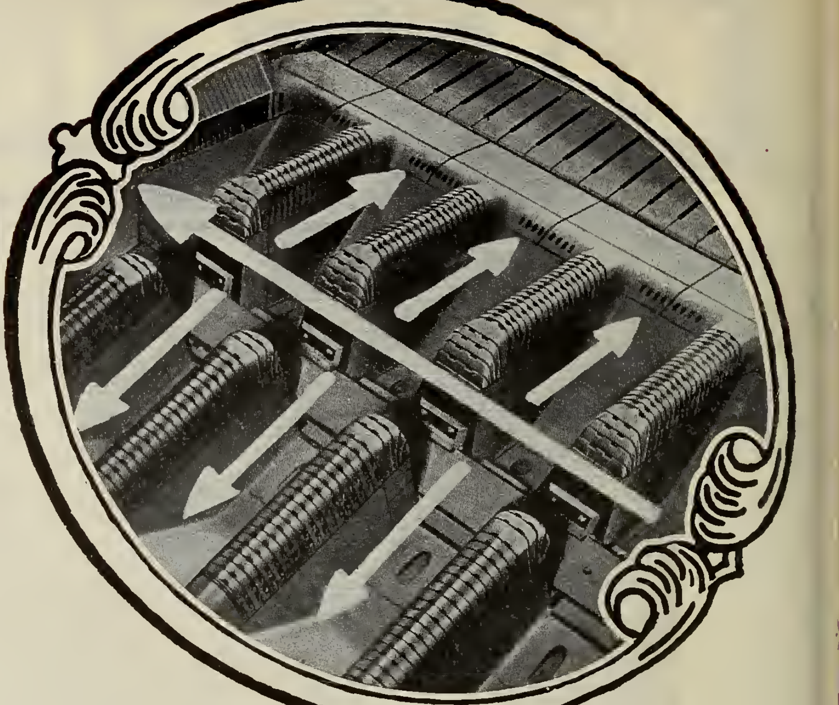
BRANTFORD, ONTARIO, CANADA



The arrows in the illustration opposite indicate the path of fuel travel in the *"Lateral Retort"** Stoker.

**"Lateral Retort"* is a trade mark.

Trade Mark

Trade Mark

Discard your old conception of single-retort stoker-firing

HERE is a stoker that has revolutionized single-retort underfeed stoker firing—one that retains the single-retort stokers high efficiency, ease of installation and low maintenance cost and yet one that combines the high capacity of multiple retort stoking.

As shown in the illustration above, the *"Lateral Retort"* Stoker has one main retort. Coal, following the path of the arrows, is underfed to this retort by successive strokes of a steam driven ram; it is then moved—still underfed—through the *"lateral retorts"* which branch off from the main retort. Finally the ash is deposited on the side dump plates from where it is dropped to the ash pits below.

One simple moving unit distributes the coal to the *"lateral retorts."*

The fuel feed to the main retort and to the *"lateral retorts"* is controlled independently; consequently ideal distribution is secured. A trench six to eighteen inches below the floor line is sufficient expansion for ash pits. This reduces the installation cost and makes the stoker adaptable to boilers already in service.

How the *"Lateral Retort"* Stoker brings the advantages of multiple retort stoker firing to plants that would otherwise install an inferior stoker is the story of the new bulletin.

The Safe and Certain Boiler Cleanser

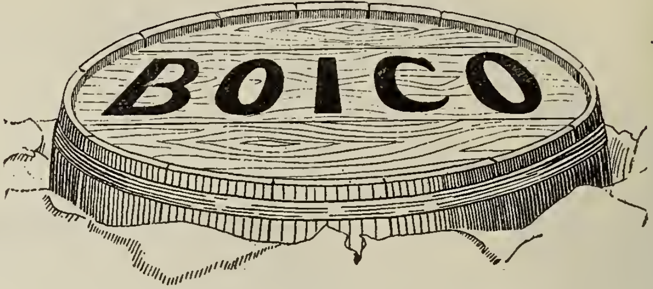
PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.**

BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.



Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

ALLIGATOR

TRADE MARK REG. U.S. PAT. OFFICE

STEEL BELT LACING

Why Men Change to ALLIGATOR

Strength comes first in belt lacing. Then follow: durability, ease and speed of application, efficiency in service, range and cost.

Alligator is the Strongest Belt Lacing on Earth—and the most permanent. It is applied with a hammer in an average time of only three minutes.

Mechanically perfect because it binds the long burden bearing belt fibres in equal service. "Every Tooth A Vise." Rocker steel hinge pin endures in any service where the belt will run. The finished joint is flexible, separable and smooth on both sides.

There is a size for every thickness of belting and the price is so reasonable that **its use immediately becomes an economy.**

If you are not using Alligator now, write us for sample and our interesting book "Short Cuts to Power Transmission." A trial of Alligator will be no less convincing than an analysis of its points.

Sold through "Jobber-Dealer" trade channels the world over.

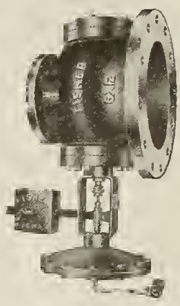
"JUST A HAMMER TO APPLY IT"

"Never Lets Go"



Your Two-Fold Duty

Steam should be saved for your employer's sake as well as for your own. For steam is coal and coal is money. When you waste you increase the cost of your work and you will eventually pay for this waste out of your own pocket in the form of higher prices all along the line.

Fisher Reducing Valve

(Type 11-A)

is a reliable aid to steam economy. It is obedient. Adjust it to deliver any desired reduced pressure and it will deliver that pressure—automatically—exactly—with no further attention on your part.

Put it to any test. It's a winner—every time.

Fisher Reducing Valve is carefully built by men long trained in their work. It is a valve that will last for many years with but little attention and repair.

Lever and weight control makes it sensitive to the slightest change in pressure.

These reducing valves are made in a wide variety of outlet and inlet size combinations. We are quite sure to have a valve in stock exactly suited to your purpose.

Write for our book, "POWER PLANT SPECIALTIES." It tells all about the complete Fisher Line.

"The Seal of Satisfaction"

BETTER REFRIGERATION

JAMISON
HAGERSTOWN MD., U.S.A.

To all the varied interests so vitally concerned in "Better Refrigeration"—architects, engineers, contractors, owners, and superintendents of cold storage plants—please note the significance of the symbol as shown above. This emblem is representative of "The Seal of Satisfaction" and reflects seventeen years of study and effort devoted to the betterment of insulating and refrigerating efficiency.

Since it is now generally recognized that "Your plant can be no better than your door;" and since the House of Jamison may rightfully claim premiership in the development of better cold storage doors, this company has adopted the above symbol and had it registered as our individual mark of merit. Hereafter the "Seal of Satisfaction" will appear upon all Jamison Products—cast in metal and firmly attached.

Let us explain the purpose and ideals of this business. If you have an interest, in any capacity, in the subject of cold storage, write for "Jamison Booklet No. 10."

How Much Coal Are You Wasting?

Blindfolding yourself to the fact that your boiler room is different, because you can see no pipe line leaks, or the water alarms don't blow very often—doesn't help to pay for the needless fuel waste caused by the invisible losses within the boiler furnaces.

Get at the REAL FACTS and at the same time give your men a positive and simple guide that will enable them to keep the plant at top notch efficiency—by installing the

BAILEY BOILER PANEL

The Bailey Boiler Panel is a combination of the Bailey Multi-Pointer Gage and Bailey Boiler Meter.

It shows, almost immediately, the effect of improper furnace adjustment and enables the men to make the necessary correction before a large amount of preventable fuel waste has taken place. Good work on the part of the men is shown up by the charts as well as any inattention. The engineer can check the efficiency of his men as well as that of the individual boiler.

Let us send you fully descriptive Bulletins.

BAILEY METER COMPANY Limited

MAGNOLIA

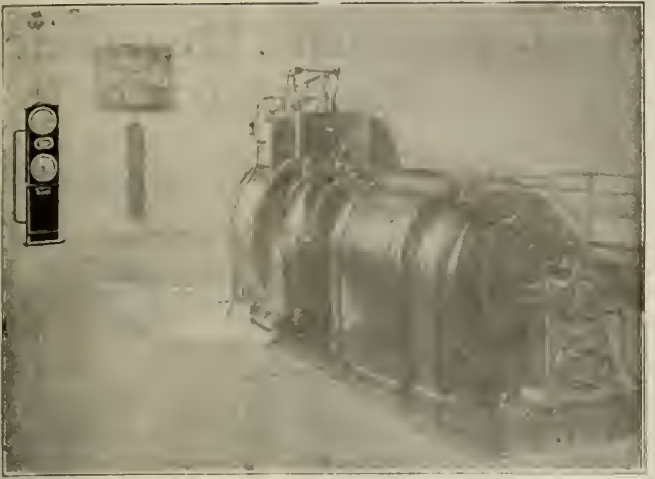
Magnolia Anti-friction Metal is the choice of thousands of engineers and machinists because it is always uniform in composition, dependable in service, melts and pours well, is widely adaptable, and assures cool-running, efficient and economical bearings. Government tests prove it to have the lowest frictional coefficient of any known bearing metal. Write for test data.

Magnolia Metal Company, 113 Bank Street, New York
CHICAGO SAN FRANCISCO MONTREAL

REG. U.S. PAT. OFF.

ANTI-FRICTION METAL

THE VENTURI METER GROWS
WITH THE PLANT



Turbine Room, D. Goff & Son, Pawtucket, R. I.

When new boilers are added to the power plant old auxiliaries often have to be scrapped and new ones purchased. Not so with the Venturi Meters.

The measuring capacity of a Venturi is easily changed, at slight expense, by substituting a new throat section in the Meter Tube and new dials in the Register-Indicator-Recorder. Some Venturi Meters have been altered several times during their long term of service without impairing their accuracy to the slightest extent.

The Venturi Meter is used to measure boiler feed water, steam, condensation from heating systems, circulating water to condensers, etc., in the modern power plant. It is accurate, durable and positive; behind it is an enviable record of 30 years and thousands of successful installations.

Shall we send you Bulletins ?

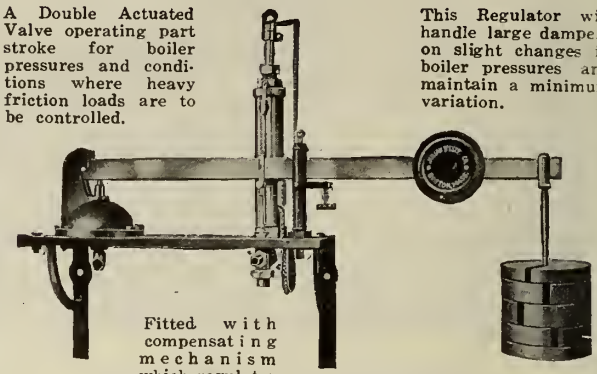
D'ESTE

Hydraulic Damper Regulator

A Double Actuated Valve operating part stroke for boiler pressures and conditions where heavy friction loads are to be controlled.

This Regulator will handle large dampers on slight changes in boiler pressures and maintain a minimum variation.



Fitted with compensating mechanism which regulates opening and closing.

Our Catalogue No. 50 of CURTIS ENGINEERING SPECIALTIES sent on application.

Julian d'Este Company

Main Office: 26 Canal St., Boston 14, Mass.

Even if you put

A water tender on every boiler—

—every man working his best to feed only one boiler—even then you could not get the safety, and the fuel savings, that are assured by the COPES System of Boiler Feed Regulation.

Careful tests between COPES feed and hand feed, in actual practice—have proved again and again that the fuel savings and labor savings of the COPES pay back its cost many times over.

The COPES varies the feed water instantly, according to every change in load conditions.

It is simple and strong with no uncertain features of construction—no springs or diaphragms, no floats or displacement bodies. The only parts are a sturdy expansion tube and a balanced valve. There is no chance for sticking or lag.

Its **reliability** has made the COPES the standard—it is used by 98 per cent. of the leading Central Stations.

Our new booklet "Regulating Boiler Feed Water" shows how marked savings in fuel—2% to 8% ordinarily—can be effected by COPES Regulation.

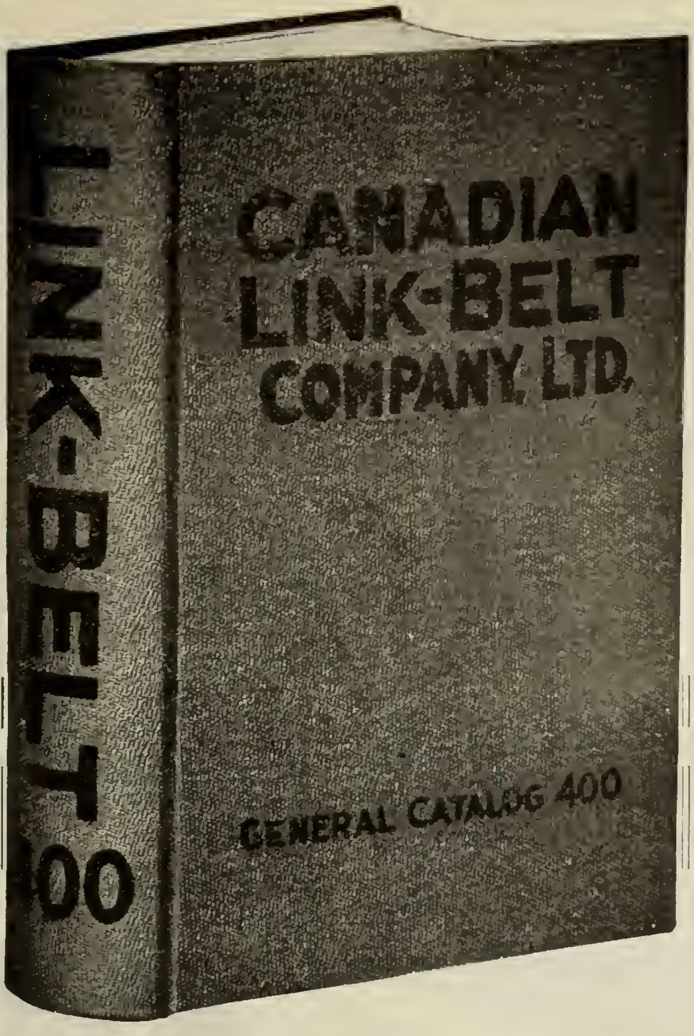
COPES
SYSTEM OF BOILER FEED CONTROL



NOW READY FOR DISTRIBUTION

THE new Link-Belt General Catalog No. 400 contains 832 pages of practical mechanical information on elevating, conveying and power transmitting machinery and accessories — chains, sprocket wheels, buckets, gears, screw conveyors; in fact, it combines the complete Link-Belt products with those of our H. W. Caldwell & Son Co. plant, now owned by our Company.

It is the most complete catalog we have ever issued. Use it as your guide in preparing plans for your material handling and power transmission equipment.

Engineers, architects, superintendents, purchasing agents, and those responsible for production, should have a copy. We shall be pleased to send the book to the right man in your organization, if it can be used to our mutual advantage. Address our nearest office, on your letterhead, giving your name and position.

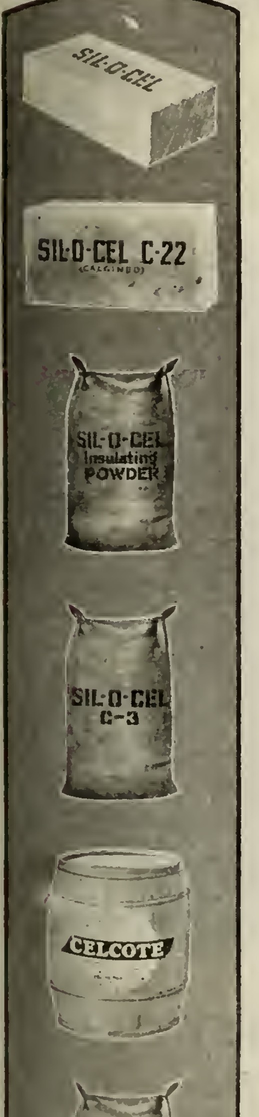
CELITE PRODUCTS
—Barriers to Industrial Waste



SIL-O-CEL
SIL-O-CEL C-22 (CALCINED)
SIL-O-CEL Insulating POWDER
SIL-O-CEL C-3
CELCOTE
SIL-O-CEL Insulating CEMENT
FRAXITE High Temperature CEMENT

SIL-O-CEL INSULATING BRICK— prevent heat loss through furnace walls and on all types of high temperature equipment. An effective and economical insulation with an exceptionally low heat conductivity. Easily applied; low in cost; a permanent insulation.

SIL-O-CEL C-22 (Calcined) BRICK— a semi-refractory type of insulation free from shrinkage at temperatures in excess of 2000° F. Used as an insulating backing in high temperature zones of oil fired boilers and other equipment operated in excess of rating.

SIL-O-CEL INSULATING POWDER— less than one-tenth as conductive of heat as an equal thickness of fire brick or red brick. Used between fire brick and steel shells or red brick walls: is sufficiently elastic to absorb expansion and contraction strains; does not settle out or shrink.

SIL-O-CEL C-3— a calcined insulation in granulated form especially adapted for use in hollow wall spaces, foundations, pans or other parts of high temperature equipment. May be used alone, or bonded with 20 per cent. by volume of Portland cement to produce SIL-O-CEL C-3 Concrete.

CELCOTE— a plastic, bitumastic compound, especially prepared for application to the brick surfaces of heated equipment, to prevent air infiltration, and also as a waterproofing. It adheres firmly to the brick and mortar, remaining permanently elastic; expanding or contracting with the surface to which it is applied. CELCOTE will not dry out, become brittle or lose its effectiveness with age.

SIL-O-CEL INSULATING CEMENTS for insulating irregular surfaces where SIL-O-CEL Brick or Powder cannot be used. These cements have great covering power and can be applied to any character of surface; they possess the insulating properties of SIL-O-CEL and are unaffected by temperatures which ordinarily destroy other forms of plastic insulation.

FRAXITE— (High Temperature Cements)—a bonding cement scientifically compounded for setting and facing fire brick work of all types of furnace construction. Furnished in three grades of various temperature ranges. Fraxite prevents fire brick from cracking or spalling and greatly lengthens the life of the entire refractory structure.

Detailed information, samples and installation blue-prints on any or all Celite products gladly sent on request. Check the coupon or ask for Insulation Folder W-6.

Parliament Buildings, Regina, Have Model Plant

Designed for Maximum Efficiency—R. H. Blackburn, Chief Inspector of Boilers in Saskatchewan, Also Responsible for Lighting, Heating and Maintenance of Power Equipment

By Special Correspondent

THE power plant of the legislative buildings of Saskatchewan is certainly a model of what such a plant should be, yet at the same time it does not present any extravagant waste of public money as the maintenance and efficiency have been a dominating consideration in carrying out the design. In this case the designers have not been actuated by the principle that to obtain the maximum of efficiency the maximum of ugliness must of necessity pervade the design.

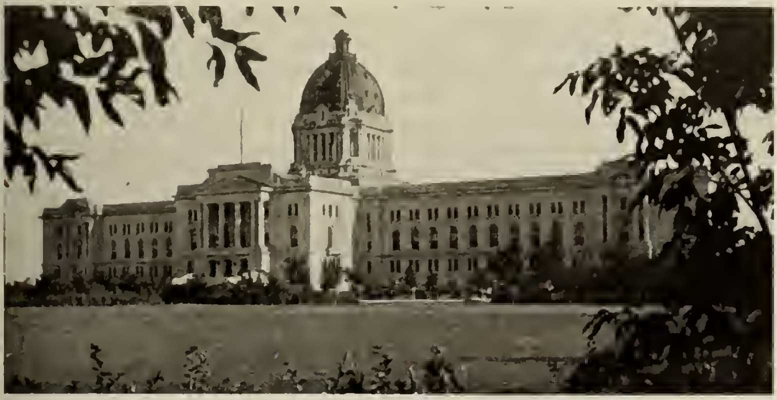

Fig. 1—Parliament Building, Regina.

R. H. Blackburn is chief engineer for the Department of Public Works, Saskatchewan, and although Chief Inspector of Boilers, he is also responsible for the lighting, heating and general maintenance of the power plant at the Parliament Building.

Mr. Blackburn who was born in Liverpool, England, in 1866, took up his scientific studies at the Liverpool School of Science. Here he won the Lord Derby Prize in 1886 for the highest marks in the South Kensington Examination. This he quickly followed up in the same year, winning the Thompson Exhibition for Mathematics and Science for Lancashire and Cheshire. Not being satisfied with these results, Mr. Blackburn also won the Whitworth Scholarship in 1887, thereby earning the title of Whitworth Scholar (Wh. Sc.) one of the most highly prized titles in the engineering profession in Great Britain.

Following upon these scholastic triumphs, Mr. Blackburn served four years aprenticeship in the workshops of George Forester & Co. Ltd., Vauxhall Foundry, Liverpool, followed by one year in the drawing office. Leaving his old firm, Mr. Blackburn took a position as draughtsman with Thornwell & Warham Ltd., Burton-on-Trent, and subsequently became chief draughtsman and designer to the company, acting in this capacity from 1891-1896.

Resigning his position in 1896, he started business for himself as consulting engineer in Liverpool. In this capacity he made quick headway when his health failed him in 1903. Acting upon medical advice, he gave up the engineering profession and came out to Canada with the object of going in for farming out West. Regaining his health, Mr. Blackburn began to again take an interest in engineering matters, and frequently gave the local community the benefit of his wide experience and knowledge. The Government in 1908 finally attracted him into their service, and in 1911, be assumed the duties of his present office.

In Saskatchewan the water conditions mitigate very materially against the efficient operation of boilers. These conditions have had Mr. Blackburn's special attention, which he felt was necessary for the benefit of the boiler owners. He consequently made a profound study of the water supply, and has upon several occasions, read papers before the Engineering Society of Saskatchewan University, and also the local branch of the Engineering Institute of Canada.

The water supply (for boiler purposes) is frankly bad. Here is given a sample of Mr. Blackburn's findings:

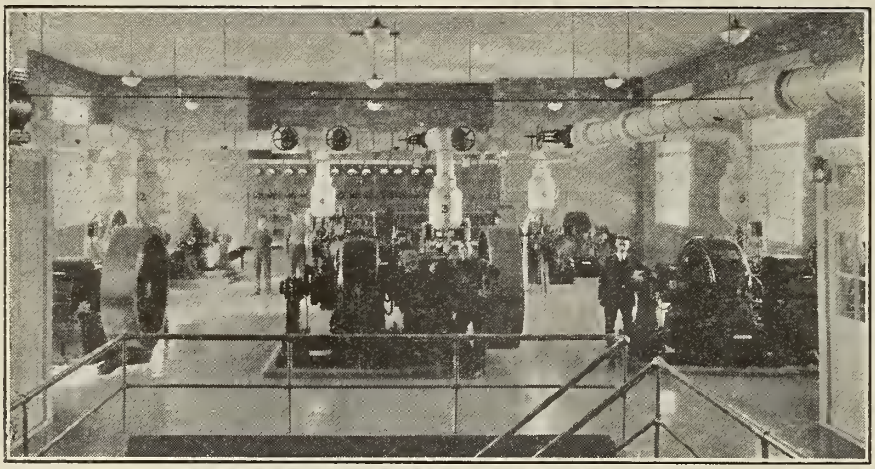

Fig. 2—Engine Room.

Mr. Blackburn is also Chief Examiner of Engineers for the province of Saskatchewan, and apart from the examination of boilers, has also under his jurisdiction the examination of gas tanks, reservoirs and compressed air tanks, all of which must be annually inspected by the Government Inspectors.

It will, therefore, be seen that independent of being chief engineer of the steam plant at the Government Building, Mr. Blackburn is also responsible for a very big department which must entail no small amount of work. Mr. Blackburn is a "big man" with a "big job" and it will be generally admitted that he handles it in a "big way."

The power house is situated some two hundred yards between the Parliament Buildings connected by a tunnel which is about six feet deep and four feet wide, this being constructed of wood and finished with cement. The electric cables are arranged in wide open steel troughs, about 4 ft. from the ground level, running down one side of the tunnel whilst along the opposite side are arranged the steam pipes supplying the steam for heating the main buildings. The tunnel is well drained and lighted with numerous bulbs suspended from the ceilings. In the event, however, of any repairs being necessary to either cables or steam pipes, there is ample working space and splendid illumination which considerably facilitates the labors of the men engaged in such repairs. This arrangement also tends to reduce the liability of breakdown, since the system permits the further inspection of these parts under the most ideal working conditions and furthermore, the economy resulting from this arrangement amply repays for the extra cost.

The general appearance of the exterior of the power house is that of a trim, clean, well designed, brick manufacturing plant, with numerous wide and lofty windows on all sides. It is a single story building about 125 ft. long and some 55 ft. wide. The first impression that one receives upon entering the engine room is the smart cool appearance and secondly the absolute freedom from noise, vibration and odour. The walls are finished in dark olive green bricks which from the floor to a height of 6 ft. these bricks are glazed and above this level they are of the usual finish. The flooring is cement finished and painted, and with the steam pipes lagged and white enamelled, the whole present a very clean and pleasing appearance.

One of the features of this power house which is much appreciated by the whole of the staff is a fully equipped bath room with full sized porcelain bath and overhead shower, with the usual hot and cold water and hand wash bowls. These are arranged in a spacious private room of white enamel finish located in one corner of the engine room.

The engine room consists of the following units:

6—100 K. W.—D. C.—compound wound dynamos. These machines generate 300 amperes at 250 volts and 275 revolutions per minute. As they operate on a three wire system of distribuion which necessitates a system of balancing the circuits, they are provided with slipperings in addition to the commutator. Special tappings are taken from the armature of these slips, the current so collected being passed to special compensating coils and so controls the out-of-balance current, without the necessity of employing either storage battery or motor generator balancers.

The engine attached to each dynamo is of the horizontal non-condensing type provided with the flywheel governor, operating a balance regulating valve which provides a very delicate regulation and is most sensitive to any fluctuation of load. The lubrication system is very complete and efficient, the whole of which being completely enclosed. The lubrication is effected by means of an oil tank fixed in a room adjoining the engine-room and elevated about 25 ft. A large oil level indicator is mounted on the wall inside of the engine-room which can be seen from all parts. From this tank the oil is distributed to each engine, passing through a system of pipes

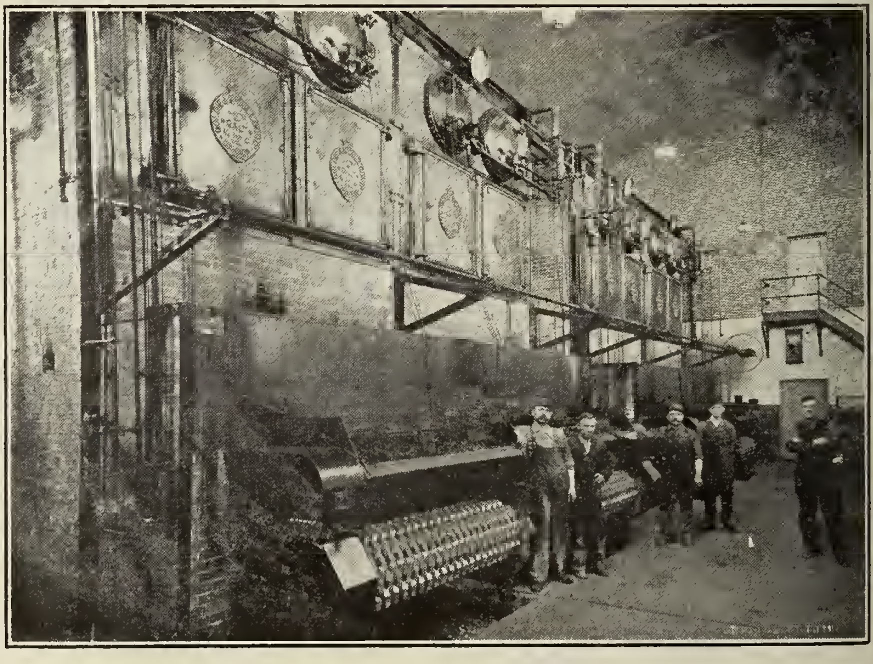

Fig. 3—Boiler Room.

to the necessary parts of the engine, and finally falling into the crank case. When the oils reach a certain level in this crank case it overflows through a pipe into a separating and cleaning tank in the basement and from there is pumped back into the tank above the level of the engine-room.

The switchboard is one of the main features of the engine-room, it being about 30 ft. long and 7 ft. high. It is mounted upon a gallery about 3 ft. above the engine-room floor. The board itself being made of unpolished black marble and consisting of 6 generator and 3 feeder panels. Each generator panel consist of two integrating kilo-watt hour meters, one being connected between the positive main and the neutral, and the other between the negative main and neutral.

2 automatic circuit breakers connected in a similar manner to the meters. These circuit breakers will open automatically, either on overload, or no-load and are "set" to open at 450 amperes.

1 shunt rheostat is provided to regulate the voltage of the dynamo.

2 double pole knife switches, one for each side of the 3-wire system.

1 single pole knife switch in the neutral wire.

1 four socket plug switch for connecting with the main station voltmeters.

2 main volmeters, one for each side of the 3-wire system are mounted about 2 ft. above the centre of the main switchboard and can be easily read from all parts of the engine-room.

The feeder panels contain the main double pole switches for controlling the feeders on each side of the system, the fuses controlling these circuits being mounted at the back of the board such that in the event of one of them "blowing" no damage can result to the operator on the switchboard gallery.

Access to the rear of the switchboard can only be obtained by passing out of the engine-room to an adjoining room, unlocking a door, and walking up 3 steps into a bricked passage some 30 ft. long, and about 6 ft. wide. Care and forethought is in evidence by making this provision, since not only is it a sound safety device, but it also provides ample space for the operators who may have to make adjustments at the back of the board whilst the plant is in operation and the board is "alive."

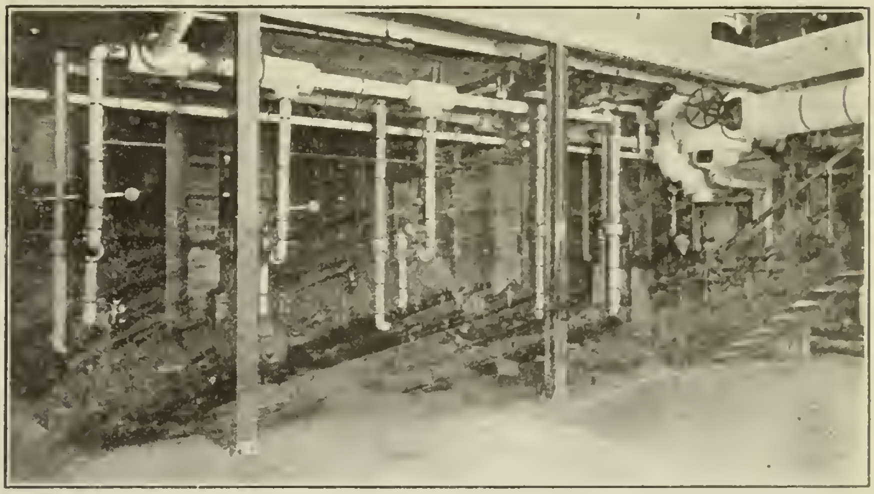

Fig. 5—Feed Pump Room.

At the end of the room opposite to the switchboard is a small chart room. In this room is mounted a water recorder of the "V" notch type for keeping a continuous record of the water consumption. There is also a steam pressure and feed water temperature recorder, a heating range vacuum gauge, heating range exhaust and 2 water pressure gauges.

These instruments are all nickel plated and mounted on polished hard wood board.

In this room the records are kept with sets of hourly and daily readings entered in the log.

These records showed a wonderful regular and even series of results. The amount of water evaporated per day was very regular running about 27,770 gals. per day, whilst the coal consumption was remarkable in its regularity which was about 27,980 lbs. per day. From this it will be observed that the evaporation runs steadily in the neighborhood of

$$\frac{27{,}770 \text{ gals. per day} \times 10}{27.980 \text{ lbs. of coal}} =$$

9.99 lbs. of water per lb. of coal.

Another interesting feature was the constancy of the steam pressure. Several charts were shown with only a variation of about 3 per cent, during the 24 hours, and one chart in particular shown only a variation of 1½% in the steam pressure during a period of 24 hours.

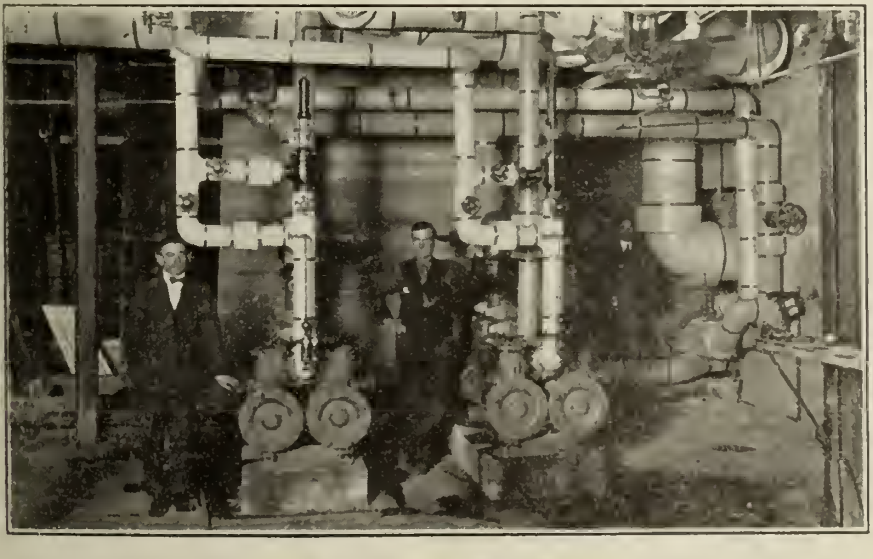

Fig. 4—Service Pump Room.

Boiler House

This is the department where some of the greatest of the economies of the plant are to be effected and if not, it would be useless trying to effect economy in other ways. Here we have two boilers of the Goldie-McCulloch type, each with two steam drums 36 in. diameter by 21 ft. 6 in. long, 112 tubes 18 ft. by 4 diameter where with a working pressure of a 100 pounds. These boilers are fitted with chain grate stokers operated with a 4 horse power motor, the shaft of which working the adjustable feed bar through an eccentric upon a ratchet. The ashes are handled through a tunnel and lifted by an ash hoist operated by the 3 h. p. electric motor.

The boilers are operated on the induced draught principle, the hydrostatic gauge usually indicating 1 in., whilst the dampers are automatically regulated by the steam pressure. The engineer claims he obtains almost smokeless combustion, although the coal is of the lignite variety obtained from Drumheller and is one of the most difficult problems to be solved. By having induced draught it obviates the necessity of spoiling the landscape by having a tall chimney stack.

Pumps

The pumping system is very complete and is divided into sections as follows:

2 duplex double ram service pumps, supplying water to all the buildings at 45 lbs. There is no tank or reservoir, and these pumps "cut in" automatically.

2 duplex double ram pumps are used for supplying the feed water to boilers.

3 air pumps in operation on the heating system for clearing the system of excess air.

Feed water heater takes in the water at 160 F. with an outlet temperature 208 F.

Water Softening

On account of the local conditions and the extremely hard water employed it is necessary to pay particular attention to this section of the plant.

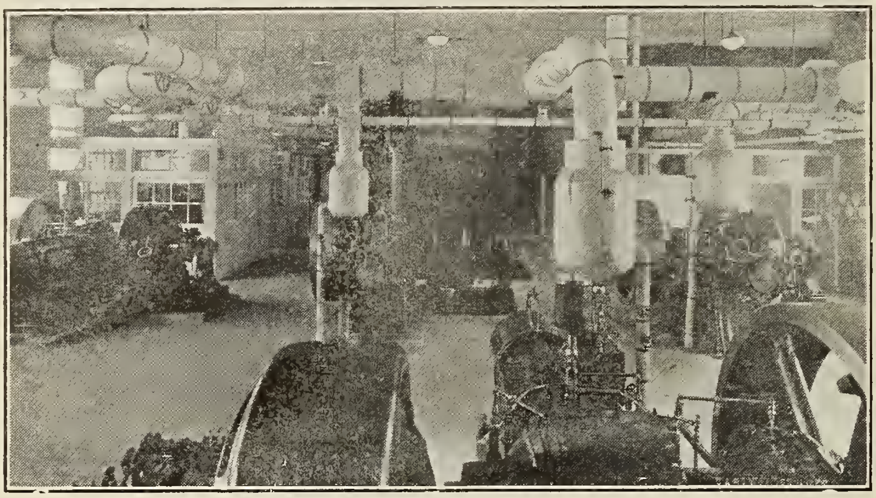

Fig. 6—Engine Room.

The water softening plant consists of 2 units and each consisting of a softening tank 60 in. diam. containing refinite.

Refinite is a trade name and is a natural double silicate of aluminum and soda. After the refinite has served its purpose in softening the water, it can be regenerated and used over again. For the purpose of regenerating the refinite there are provided two brine tanks, one for each unit. These brine tanks are 66 in. in diam. and 38 in. deep. The process is as follows: The raw water in passing through the bed of refinite in the softening tank, converts the carbonates and sulphates of calcium and magnesia into carbonates and sulphates of soda. This action is continuous until the sodium in the refinite is replaced by the calcium and magnesia when the refinite must then be flooded with a strong solution of common salt for 8 hours. This salt solution converts the calcium and magnesia into chlorides, which are soluble, and the calcium and magnesia are replaced by sodium. This is then washed free of all the salt solution and then used again.

Each unit is used alternately, one unit softening, whilst the other unit is regenerating. In this plant 150 lbs. of salt are required to 310 gals. of water for the regeneration process and every 6th regeneration it is necessary to increase the strength of this brine bath to 280 lbs. of salt to the same quantity of water.

Each unit will soften 7,000 gals. of water with one regeneration and each unit also will soften 12 gals. of water per minute.

The chemical composition of refinite is as follows:

$2SiO_2 - Al_2O_3 - Na_2O - 6H_2O$

Chemical process in softening:

Na_2 R(sodium refinite)+$Ca SO_4$=Ca R (calcium refinite)+$Na_2 SO_4$

Chemical process in regeneration:

Ca R+2Na Cl = $Ca Cl_2$+Na R.

Heating

This is provided by the exhaust steam from the main engines in the power house, and is conveyed by 16in. steam mains via the underground tunnel from the power house to the Parliament Buildings 200 yards distant.

This is accomplished by an air washer, humidifying and ventilating system, the equipment consisting of:

4 plenum fans 6 ft. diam. driven by an electric motor 20 h. p.

4 exhaust fans 6 ft. diam. at top of the buildings.

There are 4 electric elevators (passenger).

There is 1 electric elevator (freight).

On account of the pump room being at a lower level than the sewer it is provided with two vertical centrifugal pumps directly connected to two small 2½ h. p. electric motors. These are worked by a float which rises as the water rises in the well and which float lifts a plunger which operates a starting switch, which, in turn, starts up the motor. When the water has fallen back to the normal level this plunger drops, knocking out the switch and so stops the pumps.

Mr. W. Buttrey is the engineer in charge of the power house. He holds a first class certificate, and is an ardent student of engineering science, judging from the display of high class technical books in his bookcase at his office in the power house.

Summing all up, one can only say that the power plant of the legislative buildings of Saskatchewan is a credit to all concerned, and reflects in every apparatus the interest that is taken by the "man at the top."

EFFECT OF NICKEL ON STEEL

The addition of nickel to steel produces a number of improvements in its properties by reason of certain specific effects which it exerts on the structure of the steel:

1. Nickel dissolves in solid solution in the ferrite of steel and thus increases its hardness and strength without corresponding loss of ductility. Nickel steels, of all alloy steels, are unique in that they are used both in the heat-treated and in the unheat-treated state.

2. Nickel depresses the critical temperature or heat treatment range of steel.

3. Perhaps partly by reason of (2) the presence of nickel in heat-treated sorbitic steel increases the elastic limit and hardness without decrease of ductility; in other words, nickel increases the toughness of heat-treated steel.

4. Nickel exerts an influence on the grain size of ferrite and pearlite, tending to produce a finer grain structure and finer pearlite, shading into sorbite. In the same sense it diminishes the rate of grain growth within the heat-treatment temperature ranges and thus minimizes the danger of overheating during heat treatment.

These properties, both singly and in combination, are taken advantage of in several ways in metallurgical design. The depressed critical range enables the use of lower temperatures in the heat treatment of nickel steel. This, of course, means conservation of fuel and longer life of the heat-treating equipment.

It is also well recognized that the lower quenching range induces less warpage. The low hardening range of nickel steel in part explains its great popularity as a gear steel in these days when the requirements for quietness in transmission and rear axles are very exacting.

Since nickel increases the strength of steel without corresponding loss in ductility in the annealed or in the rolled or the drawn state, it is especially suited for difficult and important stampings to be used either as drawn or in the heat-treated condition. This feature also makes its use popular in the cold-drawn condition for important bolts used without heat treatment in order that the threads may be left in perfect condition, as well as for studs, nuts, keys, etc., and in the form of 3½% nickel tubing for propeller shafts, axle tubes and other structural parts.

In the heat-treated condition its superiority is well recognized for use in difficult construction where high physical properties are required. It is in this state that the high nickel content steels, and those with nickel in combination with various other alloys, give the en-

(Continued on page 36)

System of Pulverized Coal Meets Specific Needs

Twelve Million Tons of Coal Burned Annually in Pulverized Form—Many Advantages Claimed Apart From Actual Economy —Description of Equipment Used in Different Processes

By W. B. Roberts

THE application of pulverized coal to boilers and the progress made of late years has been primarily due to the great effort that has been made to obtain a more complete understanding of the subject, more particularly in respect to the preparation and handling of the fuel to meet with certain specified needs. It has been the slow development of a process of furnace firing that practically had its inception more than thirty years ago when powdered coal was utilized in the manufacture of cement. To-day there is upwards of twelve million tons of coal burned annually in powdered form. Its application to steam boilers, however, has demanded somewhat radical changes in the design of the furnace and combustion chamber, to meet with certain requirements of the boiler room. The original crude equipment has gradually been superseded by specially designed appliances with a view to promoting greater furnace efficiency, reduced fuel consumption and lower cost of operation.

The principle advantage of pulverized coal is that the coal particles are so finely divided that they readily mix with the oxygen for combustion, thereby only requiring the minimum amount of air. With large pieces of coal on the grate, as in ordinary firing, a large excess of oxygen is required to pass through the fuel bed as only a part of the oxygen can come in contact with the coal. This oxygen carries along with it four times its volume of inert nitrogen, which along with the unused oxygen, must be heated to the temperature of the furnace. The effect of this is to reduce the flame temperature, and as the gases have a large heat carrying capacity, they carry off as waste, to the atmosphere, large quantities of heat. Powdered coal when mixed with the proper proportion of air, burns without smoke and in many ways resembles the flame from ordinary gas, either the reducing or oxidizing flame being obtainable.

Apart from the actual economy effected in combustion, there are other advantages claimed, some of which are: ability to use coal of low grades and to take care of peak loads instantaneously; ease in removing ash without interruptions and losses due to opening the furnace door to clean fires; absence of moisture from the fuel as fired. Due to the reduction of air excess, there is also the saving in stack losses and power consumed by the fans; the ability to utilize 98 per cent. of the total combustible matter in the fuel, even in small installations. The experience gained at the Atlantic Steel Co. showed that a boiler efficiency of 85.22 per cent. was obtainable, of 79.22 per cent. after deducting 6 per cent. for cost of coal preparation, whereas the highest net efficiency they had obtained with stokers was 78.04 per cent. In general, the use of pulverized coal has established itself in a system as clean and flexible as oil or gas fuels, and it furthermore can be adjusted to any uniform rating that the power of the factory demands.

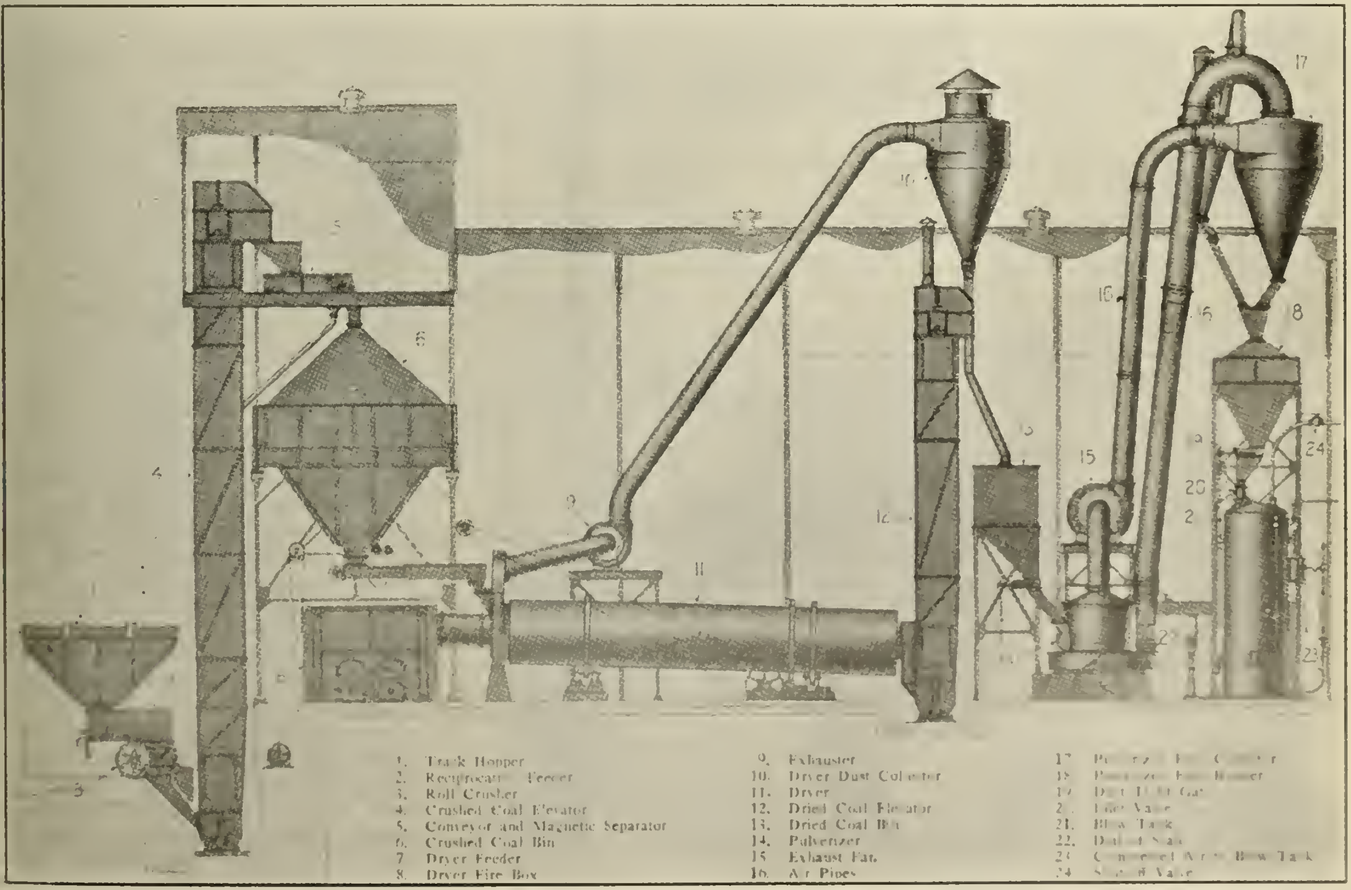

Fig. 1—Quigley Pulverized Fuel Equipment.

Against these apparent advantages must be considered the cost of preparation of the coal. One authority calls attention to the fact that various units or installations may operate at almost double the estimated cost of preparation of pulverized fuel, whilst there are forms of stokers that operate at 1/10 of 1 per cent. He also states that pulverizing equipment should be in duplicate, to avoid shut-downs; that original moisture may possibly run as high as 40 per cent. thereby increasing the cost of drying, and that fuel costs would have to be 50 to 100 per cent. higher, or pulverizing costs less to justify the use of the system. Other difficulties are the possible dissemination of fine dust over the neighborhood; trouble from slag on tubes or in ash pit; the necessity of large combustion chambers; damage to linings from high temperatures produced and the scouring action of the fuel ash; and the space required for the machinery in preparing the powdered coal.

Most Suitable Coals

It is generally understood that the greater the amount of volatile matter that is of a combustible nature in the coal, the more readily will it ignite and burn, and the less dependent will the process be upon the proportions and size of the combustion chamber. As the volatile contents decrease, greater attention must be placed upon the proportions and design of the surrounding brick work, such that the temperature of ignition can be maintained and depended upon. For instance, when anthracite coal is used, it has to be very finely ground and burned in a very confined space so that the nearby brick-work very materially aids in insuring prompt ignition. Coals giving the most satisfactory results have been found to be those with less than 10 per cent. of ash, which was of high fusing point, volatile matter 30 to 40 per cent., fixed carbon from 40 to 50 per cent., and sulphur, not only 50 per cent., but preferably much lower.

The average analysis of coals good for pulverizing is:

Volatile matter	39 per cent.
Fixed carbon	53 per cent.
Ash	8 per cent.
Sulphur	2 per cent.
B. t. u., per lb.	13,600

In Fig. 1 we illustrate the Quigley Pulverized Fuel Equipment which is a system complete with appliances for preparing, distributing and burning powdered coal. The system will be better understood by referring to the description of the diagram.

This system includes complete equipment for the preparation, transporting and burning of powdered coal and other fuels. It has been developed as the result of 25 years' specializing in the selection and application of fuels, and in furnace design, construction and operation.

The equipment used for preparation of fuel, crushing, drying, pulverizing, etc., is, in the main, standard equipment as used for this purpose in many plants now burning coal in pulverized form. The system of distribution from milling plant to furnaces, however, differs from the screw conveyor and high pressure blast system, in that the fuel is transported in bulk from the pulverizing plant through a small diameter standard wrought pipe to bins located at the furnaces. Delivery is being made by this method for distances exceeding half a mile; the extreme distance is dependent only on the capacity of the equipment used.

The pulverized fuel is fed into a blowing tank which rests on a scale. This automatically weighs the amount in the tank. Compressed air is then admitted to the blowing tank with the result that the fuel flows in bulk along the transport line and is switched from this line by means of specially designed switching valves to the furnace bins. By reading the blowing-tank scale before and after the sending of fuel to any particular bin, the amount of fuel transported can thus be recorded and charged against the operation of the furnace or furnaces which this bin supplies.

From the furnace bins, the fuel passes through a dust tight gate into a specially designed fuel feed regulator or controller, by means of which the operator has immediate and absolute control of the fuel fed to the furnace. The mere turning of a hand-wheel, the operation of which is like that of an ordinary valve, enables very close adjustment of fuel fed to the burner and the operator can, in an instant, secure any condition of flame desired.

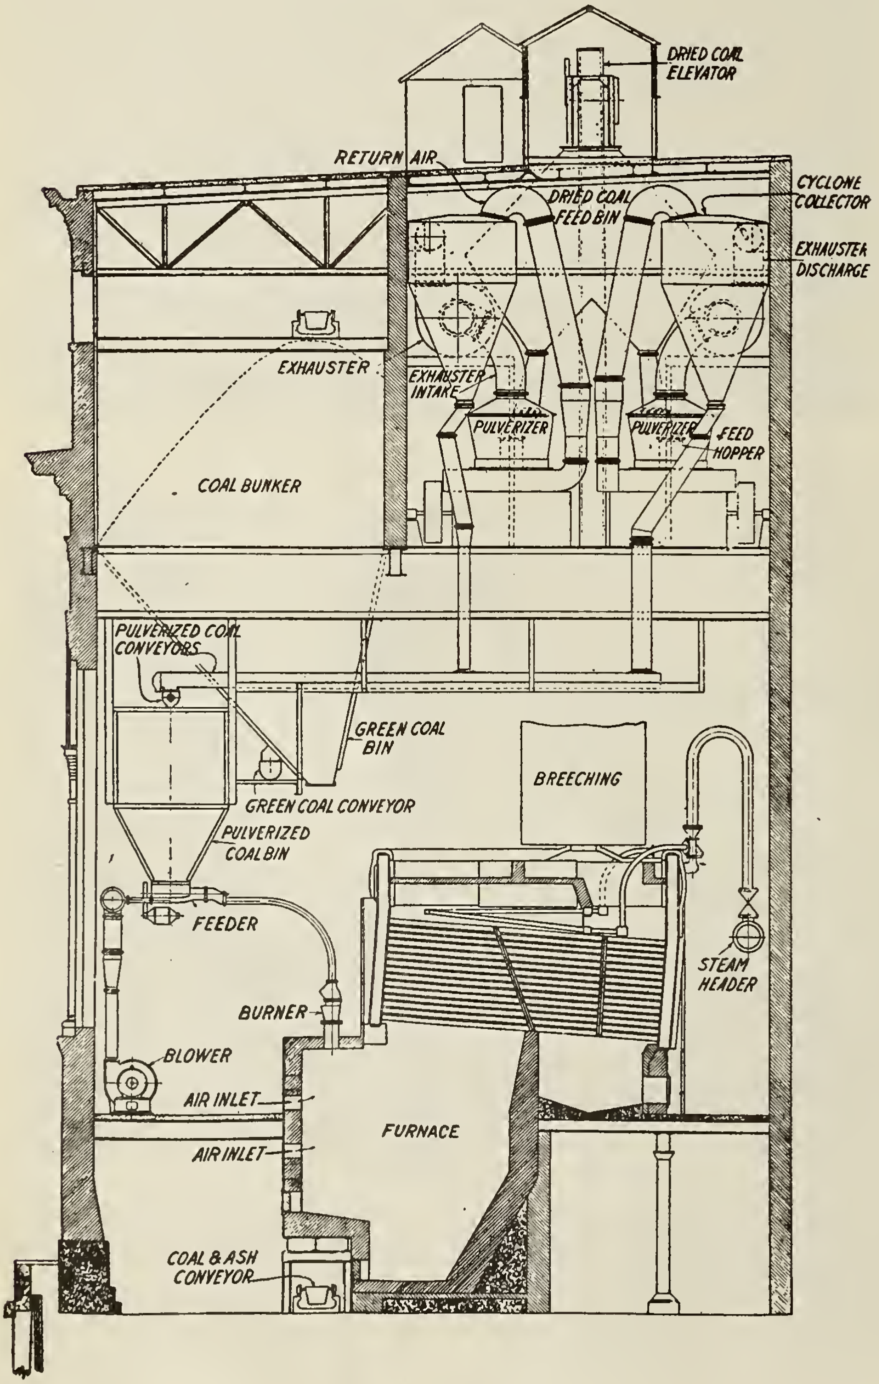

Fig. 2—Cross section through Oneida Street Boiler Plant of Milwaukee Electric Railway & Power Co.

By operating the control gate attached to the bottom of the pulverized coal bin, the fuel enters the blow tank in the desired quantity, and the gate is then closed. The operator makes a record of the amount of fuel in the tank and then admits air for driving the fuel in bulk through the 4 in. diameter distribution mains. By means of switching valves appropriately located along the fuel distribution lines, the coal can be diverted into any furnace bin desired, and the amount of fuel transported, as indicated by the scale dial, is charged against the furnace served by the bin to which the fuel has been sent.

The air for transporting the coal is supplied from a motor-driven air compressor. A receiver for storing the compressed air is located adjacent to the compressor and suitable means are provided for drying the air before it is used for transporting the fuel. The switching valves for diverting the fuel from the transport line to furnace bins, are operated from the floor by hand chains.

Furnace Bins

All bins are of steel plate, entirely enclosed and dust tight. In order that the furnace operator may determine the amount of fuel available for firing, each furnace bin is provided with a fuel gauge, having an indicator conveniently located.

When more fuel is required in any particular bin, the operator at the milling plant is notified, the switching valve is set for delivery, and the desired amount of fuel blown through the transport line, the milling plant operator recording the amount as shown on his scale dial.

Dust Tight Gates

All furnace bins are provided with one or more dust tight gates for regulating the fuel passing to the controller. These gates are of heavy construction, enclosed in a cast iron body, and are operated from the floor by hand chains.

Controller

The controllers are attached to the dust tight gates directly beneath the fuel bins. The controller body consists of a substantial cast iron box and discharge head, housing an interrupted feed screw which is geared to a small shaft driven at constant speed. Two shutters within the controller close over the feed screw to form an adjustable opening for regulating the amount of fuel which passes from the controller to the burner. These shutters are operated by hand chain wheels, and can be adjusted for any range of control between minimum and maximum capacity. In operation, the regulation is similar to the opening or closing of a valve, so that the operator quickly becomes proficient in adjustment.

The discharge head of the controller showers the fuel into the ejector, where it is carried along by a primary air system to the nozzle of the burner, entering the burner either at the back or side, whichever may be most convenient.

Combustion

The method of combustion operates under primary and secondary air supply. The former if small in volume and at a pressure of less than 6 ounces per square inch, draws the fuel from the discharge head of the controller, the pressure being greatly reduced in carrying the coal to the burners. The secondary or combustion air in large volume and at very low pressure (½ ounce per square inch), here mingles with it. Both primary and secondary air are under perfect control of the furnace operator by means of blast gates. The secondary air amounting to 85 per cent. of the total volume required for combustion permits the operator to produce any character of flame desired. An oxidizing or reducing flame condition may be secured at will.

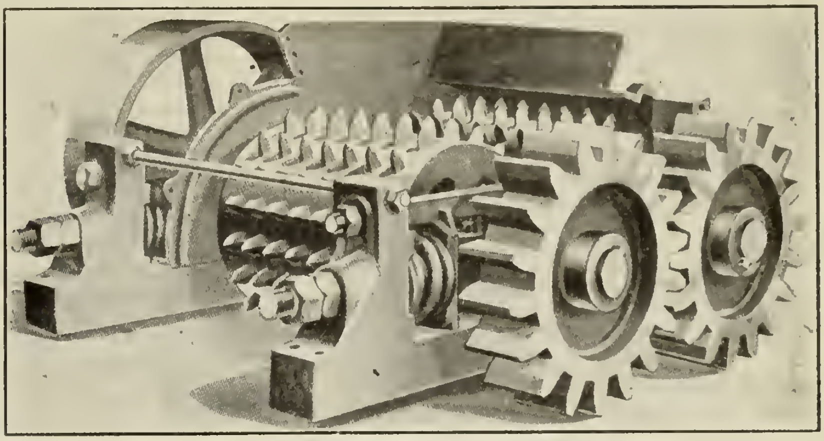

Fig. 5—Bonnot Two Roll Coal Crusher.

Burners

The burner is equipped with a specially designed air gate constructed so as to deliver the full volume of air, uniformly distributed at the tip of the burner.

Dust Tight Features

The entire powdered coal equipment in the milling plant is enclosed and dust tight. The fuel being distributed in bulk along the transport lines and being at no time mixed with sufficient air for combustion until it enters the burner, insures absolute safety of the system.

In Fig. 2 we show the first commercial installation of any considerable size, which was at the Oneida Street plant of the Milwaukee Electric Railway & Light Co., where five Edge Moor boilers, each of 500 h. p. capacity, were equipped in 1918. This plant, which is a combined heating and power plant, has been in operation for nearly five years. No unusual operating difficulties of any kind have been encountered. There have been no interruptions to service due to the operation of powdering the coal and the plant has met every requirement, including the very severe test of the winter of 1919-1920. The importance of the plant is indicated by the fact that it heats practically all of the down-town Milwaukee. This plant illustrates the ease

with which coal conditions can be met in making powdered coal installations. By reference to the illustration, it will be noted that the plant for the preparation of the coal, was installed over the boilers in a room, originally intended to house the economizers.

John Anderson describes the equipment for burning the powdered coal at this plant. The drier and pulverizers, he says, serve the five boilers which are of the three-pass, vertically-baffled type, with three drums. The coal passes from left to right through the direct-fire drier and over a magnetic separator to remove scrap metal, then through the variable speed pulverizer to the fuel bin from whence it is conveyed to the combustion chamber by two Lopulco feeders and burners with one blower for each boiler and all motor driven. The flame does not come within five feet of the ashpit door, therefore the ash collects as a carbon-free powder with only small pieces of slag easily removed.

The bulk of the air required for combustion is supplied, not through the burner, but through a number of 10-inch openings in front of the furnace. Tests made when operating at a rating of 116 per cent. showed a net efficiency of 85.22 per cent. on 10,779 B. t. u. coal received with 10½ per cent. moisture with an equivalent evaporation of 9.47 lb. per lb. of coal and an average of 13.85 per cent. CO_2 and no CO. The fuel for the drier and power for conveyors and pulverizers cost 26 cents per ton of coal treated, representing 4½ per cent. of the coal, and giving a net efficiency of 81 per cent. The boilers used were originally built for burning solid fuel, the only changes required being the addition of a mixing oven in front of the boiler and the rounding out of the corner formed by the door of the ashpit and the bridge wall. The furnace volume is 1,700 cu. ft. and with the proper air supply, there is no overheating or damage to the brickwork.

It might be of interest, at this stage, to see the actual results obtained from ordinary working conditions at such a plant and we give in tables in Fig. 6, a summary of several tests conducted over a period of ten months. These were tests made under actual operating conditions by Mr. H. Kreisinger under the Fuel Section of the United States Bureau of Mines in co-operation with the Research Department of the Combustion Engineering Corporation. The powdered coal equipment was designed and installed by the Locomotive Pulverized Fuel Co. The coal burned at these tests came from the Illinois coal field. The object of the tests was to determine what overall efficiency can be obtained with pulverized Illinois coal under various conditions of furnace operation. Conditions varied in respect of the various degrees of fineness and percentages of moisture.

It might occur to an engineer, that there is no means of banking the boilers during the period they are off. There is no difficulty whatsoever in this respect. During banked periods no coal is fired. Both the stack damper and the auxiliary air inlets are closed tightly. There is no flow of air through the furnace. The brick-work, however, acts as a regenerating medium, so that the loss of pressure in the boiler is extremely low. A boiler may be banked for more than ten hours with no coal fired and have a pressure drop during the whole of this period of not more than 20 lbs. This will be seen in table given in Fig. 5, which was an experiment conducted on No. 5 boiler over a period of ten hours.

RECORD OF OBSERVATIONS ON FURNACE DURING BANKED PERIOD AT ONEIDA STREET STATION

Date—August 19, 1919.

Boiler No. 5—Edge Moor, rated 168 nominal H. P.

Drop of steam pressure in boiler, from 9:00 p.m. until 7:00 a.m., or during 10 hours while fuel feed was off and during which time safety valves popped 15 times, for one minute each, or a total of about 15 minutes	20 pounds

A great amount of interest has lately been created in respect to the satisfactory utilization of our lignite deposits out West, for commercial purposes. The method of briquetting met with very poor success and we think the alternative will be found, after three years of success in the pulverizing of the coal, in adopting such a method which would help in the development of our natural resources and furthermore utilize such material to the best of advantage.

COAL CONSERVING

The value of hydro-electric energy as conserving coal consumption in Canada may be partly gauged by the fact that only 1½ per cent. of the total coal consumption takes place in central electric power stations. In the United States 2.6 per cent., and in the United Kingdom 9.7 per cent. of the total coal consumption occurs in the stations. In 1920 over 97 per cent. of all the power output from central stations in Canada was produced from water power. The steady growth of water-power development during the past two years indicates that this proportion will be maintained or even increased.

NO DANGEROUS STRAINS FROM SUDDEN STEAM DISCHARGES

No degree of shock whatever was shown when the effects of large sudden steam discharges from boilers were investigated by the American Society of Mechanical Engineers' research subcommittee on sudden initial pop lift safety valves. The results obtained by this committee, of which P. G. Darling is chairman, were presented at the recent annual meeting of this society. The tests were conducted to determine whether there is a shock to the boiler which under any condition may become dangerous or cause damage when a relatively large steam discharge from a boiler is suddenly stopped, as in the opening and closing of a safety valve.

The tests covered sudden steam discharges which in size, relative to boiler capacities, were far in excess of the capacity of any safety valve which would ever be attached to the boiler. With a 75-boiler-hp. Almy water-tube at the plant of the Crosby Steam Gauge & Valve Company at Boston (actual test in this case being made by the Massachusetts Institute of Technology) the maximum discharge tried was approximately three times the total safety-valve requirement of the A. S. M. E. Boiler Code. On a 94-boiler-h.p., 300-lb.-pressure Babcock & Wilcox boiler installed in the plant of the Consolidated Safety Valve Company at Bridgeport, Conn., more than seventeen times the total value capacity for the boiler was instantaneously relieved in the attempt to produce a shock. When it is considered that two or more valves would be called for by the A. S. M. E. Boiler Code, the sudden steam relief that was tested at Bridgeport would be thirty-four or more times the largest valve which would generally be used with this boiler. The locations of the pressure indicators in the Bridgeport test, selected because considered the most likely points to receive shock, are believed to be representative enough to justify the conclusion that no shock would be detected from an attachment at any other place.

In the opinion of the committee the investigation might be continued with prolonged trials on different types of boilers under different conditions of steaming, and with additional points of attachment for the pressure indicators. However, considering the fact that no degree of pressure increase or shock whatever was detected under the severe steam discharge conditions tried, the committee believes that it is extremely unlikely that any boiler conditions would be found so radically different as to produce a shock. In other words, if a pressure-increase shock could be produced by any reasonable boiler operation, the committee believe that the conditions of their tests were representative enough to insure detection of such shock.—Electrical World.

Fusibility of Ash from American Coals

The Data and Information Gained in the Investigation Upon the Fusibility of Coal Ash Should Very Materially Help the Engineer to Safeguard Against This Objectionable Condition

By W. A. SELVIG and A. C. FIELDNER, of the U. S. Bureau of Mines.*

INFORMATION concerning the fusibility of coal ash has become of considerable value to the consumer of coal, mainly in connection with the troublesome formation of clinker resulting from the melting of the ash constituents of the burning coal. The growing interest in such data has led the Bureau of Mines to make a general survey of the "fusing" or "softening" temperatures of ash from coals of the United States. It is hoped that this information, when used together with the large number of coal analyses published by the bureau, will assist the consumer of coal in comparing different coals, and in selecting the coal best adapted for his purpose.

Coal ash is the incombustible residue remaining after the complete combustion of coal; it is derived from the inorganic mineral constituents of the coal. The ash-forming constituents are (1) inherent or intrinsic impurities that are present in an intimate mixture with the coal substance, and are derived either from the original material or from external sources such as sedimentation and precipitation while the coal-forming plant remains accumulated; (2) impurities, formed either during the laying down of the coal bed or subsequently, that occur in the form of partings, veins, and nodules of clay, shale, "slate," pyrite, and calcite; and (3) impurities that become intimately mixed with the coal in the process of mining, such as fragments of roof and floor.

. . . . The fusibility of coal ash depends on several factors, such as the ratio of the silica to the bases present, the particular bases, and the percentage of alumina present. Mixtures extremely high in silica or extremely high in bases are not readily fusible. Ash that is low in iron is usually so highly siliceous that it is not readily fusible. Ash from coals high in pyrite is necessarily high in iron, and the ratio between the bases and silica is often such that easily fusible compounds may be formed. As a rule, coals containing considerable sulphur in the form of pyrite are apt to give trouble from clinker formation. Under conditions of the fuel bed the iron of the pyrite is apt to be converted to ferrous oxide, which with the silica present forms ferrous silicates that fuses at comparatively low temperatures.

Relation of Fusibility Tests to Clinker Formation

It is well to bear in mind that the conditions of fusibility tests in the laboratory may not be directly comparable to the conditions in the fuel bed of a furnace. In a laboratory test the ash-forming constituents are intimately mixed, whereas there is usually no such uniform distribution of the ash-forming constituents in coal.

Some coal ash is so fusible that little trouble is experienced from the formation of clinker. Ash that is slightly more fusible will often form a porous, spongy clinker which does not seriously obstruct the flow of air through the fuel bed and is easily removed. Coal ash with a low fusing temperature, say 2,100° F., not only melts in the average fire box but is heated several hundred degrees above its melting temperature, becoming quite fluid and spreading out in a thin sheet, over the grate, thereby obstructing the flow of air and localizing the heat in the fuel bed.

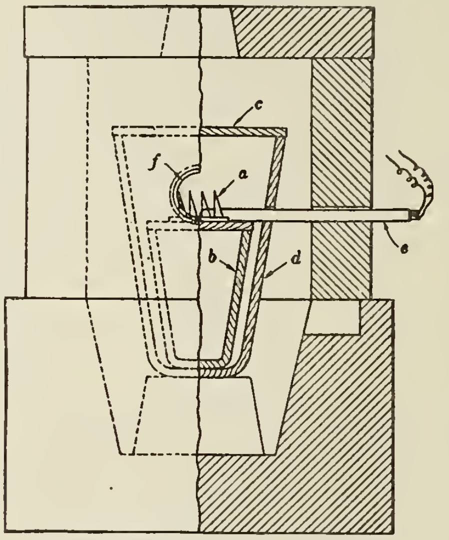

Fig. 1—Section of No. 3 melter's furnace arranged for fusion tests.

Effect of Atmospheric Conditions

The method adopted for making fusibility tests was the result of considerable experimental work, by the Bureau of Mines on the nature of the fusion of coal ash and the influence of various oxidizing, reducing, and neutral atmospheres on the softening temperature of ash molded in the form of Seger cones. The method takes into consideration the various factors that influence the result obtained, with special reference to the atmosphere surrounding the ash during the test. . . . . Analysis of clinkers from boiler furnaces indicated that fuel-bed conditions favored the formation of clinkers in which the iron was chiefly in the ferrous state; consequently the values obtained in the laboratory tests are, in this respect comparable to such conditions, and the tests give the lowest temperatures at which the intimately mixed ash will soften with the formation of clinker.

Method of Testing Ash

The interior of the furnace as arranged for making a test is shown in figure 1. The ash cones a are supported on a plate of alundum cement serving as a cover for the crucible, b, which is a Denver fireclay hard-burned crucible, No. E, 4 inches high and 3 inches in diameter at the top. An alundum tube of the proper height may be used in place of crucible b. Crucible d is a Denver fireclay hard-burned crucible, No. K, 7¼ inches high and 4⅝ inches in diameter at the top; it has observation and thermocouple holes corresponding to those in the furnace cylinder, and it rests on a fire-clay support. The thermo element is protected by a glazed Marquadt porcelain tube, e, one-fourth inch in diameter. A fused silica tube, 1⅞ inches in external diameter and 6 inches long, is placed in the observation hole of the furnace, the inner end being flush with the inside furnace wall and the other end projecting from the furnace. This crucible should be provided with two holes in the side, an observation hole 2 inches in diameter with its center 2 inches from the top of the crucible and a thermocouple hole 1 inch in diameter, 9° to the right of the observation hole. The bottom of this hole should be in the same horizontal plane as the bottom of the observation hole.

Ash Completely Oxidized

Spread out 50 to 100 grams of 60-mesh coal on a 5-inch fire-clay roasting dish, and completely convert it to ash in a muffle furnace at a temperature of 800° to 900° C. Transfer 5 to 10 grams of this ash to an agate mortar and grind to a fineness of 200-mesh. A mechanical agate-mortar grinder will save time where many determinations

(Continued on page 30)

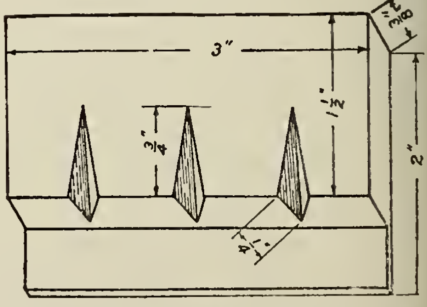

Fig. 2—Brass cone mold for making ash cones.

Factors That Influence Chain Drive Efficiency

Purpose of the Spring Cushion Wheel—Recommended Gear Ratio—Best Location of Drive—Taking Care of Slackness in Chains—Tendency to Individual Drive on Machine Tools

SPRING cushion wheels are designed for reducing the irregularities in the load on chains when driving certain classes of machinery. It is usually the driven wheel and while not occupying much more space than an ordinary wheel is considerably heavier. There is an outer toothed rim with two or more inwardly projecting vee blocks arranged equidistant. The inner portion of the wheel comprises a boss and rim with outwardly projecting vee blocks also arranged equidistant. Coil springs in partial compression are arranged between these vee blocks, one set taking driving effort and another and lighter set acting as buffer springs to neutralise the recoil when the extra compression is taken off the first set of springs. The springs are enclosed by a suitable cover plate. To keep the inverted tooth type of chain in place, guide plates may be arranged either on the outside or along the centre of the chain, though, of course when used on flanged wheels, the guide plates are unnecessary.

Recommended Gear Ratio

Horse powers from 1/10 to 5,000 have been satisfactorily transmitted by chains. The maximum gear ratio recommended for the roller type chain is 7 to 1 and for the inverted tooth type chain 6 to 1. For the roller type chain of ⅜ in. and ½ in. pitch the normal maximum chain speed in feet per minute is 1,000 and this is gradually decreased as the pitch increases so that for a 3 in. pitch chain 500 ft. per minute would be the normal maximum. In the inverted tooth type for ⅜ in. and ½ in. pitch 1,500 ft. per minute may be employed, and this gradually decreases to 1,200 ft. per minute for a 3 ins. pitch chain. These figures assume a sprocket pinion of not less than 19 teeth for the roller type and 21 teeth for the inverted tooth type. The desirable maximum centre distance expressed in pitches of chain for the roller type, ⅜ in. to ¾ in. is 100, 1 in. to 1¾ in. 85, 2 in. and upwards 70. For the inverted tooth type ⅜ in. to ¾ in. is 70, 1 in. to 1¾ in. 60, above 2 in. is 50. These figures apply for an ordinary horizontal drive with steady load or slightly inclined drive. The minimum centre distance should be such that the arc of contact is not less than 120 deg. between the chain and any wheel and with at least 7 teeth in engagement. Chain drives should preferably be arranged horizontal or inclined not more than 60 deg. when the large wheel is uppermost in the drive and not more than 45 deg. when the pinion is uppermost. These angles refer to the driving side of the chain and an horizontal line. It is important that the shafts should be truly parallel and horizontal.

Vertical shafts require special treatment. Wherever possible means should be provided for adjusting the shaft centres so that slackness due to a worn chain may be taken up. This prolongs the life of the chain. In electric drives, the slide rails of the motor make this provision. At least 1½ times the pitch of the chain should be allowed. If provision cannot be made, in the case of an horizontal or inclined drive, the chain may run slack until the slackness is such as to allow a link in the chain to be removed. Where the bottom side of a chain is the tight side, provision must be made to keep the two sides apart, hence the reason for large chain wheels in relation to centre distance. A chain works best with the tight or driving side uppermost and should be so arranged where a choice is possible. In all cases where there is a substantial amount of end play provision must be made to allow the chain to move laterally. Pinions should have an odd number of teeth if possible, in order to give uniform wear on the wheels and chain. Irregular loads should be corrected by the introduction of a flywheel and centre distance should also be short and the wheels as large as possible to prevent sagging. If a flywheel is impossible, the chain must be kept taut by adjusting the centres or the use of a jockey wheel or the introduction of a spring cushion wheel to absorb shock. Safety pins can be fitted in a driven wheel in the case of feed motions where damage may occur due to positive action of the chain. This shears in the event of an overload and allows the driven wheel to turn around on its shaft.

Cleaning and Lubricating

Lubrication of the working joints is essential for chain gearing. The most efficient form of lubrication is to encase the drive and pump a constant stream of oil on to the inside face of the chain from a filter pump, or the chain may be run through oil. This is essential for a chain speed exceeding 1,000 feet per minute. A drip feed lubricator may be used for slower speeds dripping on the inner face of chain, and a light or medium machine oil should be used. Periodic cleaning is essential.

The drive should be thoroughly cleaned and overhauled every three months and oftener if working in damp and dirty conditions. A bath of paraffin is recommended and then a suitable lubricant, tallow or grease for roller chain, light or medium machine oils for the inverted tooth type, all wearing surfaces should be thoroughly lubricated. If the chain has not a gear case, a light screen or guard may be necessary to guard against oil splashing. When the periodical examination is made it should be seen whether the chain requires adjustment, requires clearing, whether the wheels are correctly aligned, whether undue wear is taking place or whether lubrication is satisfactory. In the chain case, the chain runs through a reservoir of oil, and the level should be such that the lowest point of the chain will dip into the lubricant in its passing. The cases are divided, the upper half fitting inside the lower, and are dust-proof.

Necessary Conditions

When a chain is being renewed, it should be noted that where the drive is continuously in one direction a certain amount of wear will necessarily take place on the face of the wheel teeth in contact with the chain. Providing the wheel bosses are equal sided and bored parallel they should be reversed on their shafts to bring the unworn faces of the teeth into engagement with the new chain.

In addition to the numerous motor to lineshaft, lineshaft to countershaft and countershaft to machine chain drives which have been introduced in recent years both in replacement of existing drives and as new installations, almost every modern tool is now constructed so that it may be directly driven by motor. In this case the motor is self-contained with the machine, and the drive from the motor spindle to the driving spindle of the machine is very frequently by chain.

The invariable practice is to either mount the motor on a foundation plate connected to the machine or directly on the machine itself. Examples of both these methods are to be found in any modern engineering works, applying to the driving of lathes, planing, shaping, slotting, milling, drilling, gearcutting and other machines. The chain is also being developed for auxiliary drives, such as for driving the feed motion of a lathe, the power elevating gear for a planing machine, the quick power traverse of the carriage of shaping and various machines, tools etc. In some cases it is possible to displace quite a complicated arrangement of spur and bevel gears, horizontal and vertical shafts by a simple chain drive. Jockey wheels are employed to guide the chain past any desired point. The user is strongly recommended in any case of doubt to lay his information before any of the well-known makers of chain drives for their advice.

FUSIBILITY OF ASH FROM AMERICAN COALS

(Continued from page 28)

are made. Place the finely ground ash in a silica or porcelain capsule, about five-eighths of an inch deep and 1¾ inches in a current of oxygen, at a temperature of 800° to 850° C. The purpose of this ignition is to insure complete and uniform oxidation of the ash.

Figure 2 shows a brass cone mold for making ash cones, three-fourths inch high and one-fourth inch at each side of base, which is an equilateral triangle.

Temperature Measurements

This may be made with a thermocouple of platinum and platinum-rhodium, protected from the furnace gases by a glazed Marquadt, Usalite, Impervite, or equal quality porcelain tube and a high resistance millivoltmeter; or with an optical pyrometer preferably of the Leads and Northrup Wanner type.

Moisten the ignited ash with a 10 per cent. dextin solution, containing a small amount of salicylic acid as a preservative, and work into a plastic mass with a spatula. Mold the plastic material into small triangular pyramids three-fourths of an inch high and one-fourth of an inch wide at each side of the base. The pyramids are made by firmly pressing the plastic material with a steel spatula into a brass mold of the dimensions mentioned, the mold being similar to that shown in figure 2. Usually five cones are mounted on the refractory base. Put the test piece in the muffle furnace in the position shown in figure 1, place the loosely fitting cover c on the crucible, and ignite the gas. It is necessary to let the gas burn about 10 minutes to heat the furnace parts before the large cover plate of the furnace is replaced; otherwise the flame is apt to blow out. After the cover plate of the furnace has been put in position, the flow of gas and air is increased enough to cause combustion to take place just above the tuyeres and yet maintain a yellowish flame at least 6 inches above the opening in the furnace cover plate. While such a flame is maintained above the furnace, gradually increase the temperature by a suitable adjustment for gas and air to 800° C., then reduce the rate of heat increase to not less than 5° C. and not more than 10° C. per minute. Maintain this rate until the end of the test.

The softening temperature is defined as the temperature at which the cone has fused down to a spherical lump.

Critical points other than the softening temperature may be observed during the test and may be of value. They are as follows:

The initial deformation temperature—the temperature at which the first rounding or bending of the apex of the cone takes place.

The fluid temperature—the temperature at which the cone has spread over the base in a flat layer. Owing to the short life of the refractory crucibles used when heated to temperatures higher than 1,500° C., ashes that did not fuse at 1,500° C. were heated in a molybdenum-wire resistance furnace in an atmosphere of hydrogen gas to a temperature of 1,650° C.

Grouping of Softening Temperatures

In general, the softening temperature of coal ash from the coals of the United States ranges from 1,900° to 3,100° F. For convenience in discussion, the order of fusibility of ash may be expressed by subdividing this range of softening temperature into three groups, as follows:

Class 1, refractory ashes, softening above 2,600° F.

Class 2, ashes of medium fusibility, softening between 2,200° and 2,600° F.

Class 3, easily fusible ashes, softening below 2,200° F.

The coals of Ohio which were tested gave ash of medium fusibility, mainly in class 2. The bituminous and semi-bituminous coals of Pennsylvania that were tested gave refractory class 1 ash and medium fusible class 2 ash, chiefly the latter. Only a small number of coals from the Pennsylvania anthracite region were tested; these gave refractory ash in class 1. The semi-bituminous coals of West Virginia come principally in class 1 and class 2. Some very refractory class 1 coals are found in the Beckley bed in Raleigh County. Many of the coals of Maryland that were tested gave a refractory ash coming in class 1 or in the upper part of class 2. The softening temperature of the ash from coals of eastern Kentucky and of Virginia cover a wide range of fusibility from readily fusible ash, class 3, to refractory ash, class 1. The coals tested from Tennessee and Alabama come mainly in class 2, having ash of medium fusibility, but both class 1 and class 3 are represented. The ash-softening temperature of coals from Illinois, Indiana, western Kentucky, Kansas, Missouri, Oklahoma, and Arkansas, is uniformly low, practically all coming in class 3. The uniformly low softening temperature of the ash is unquestionably due to the rather general distribution of pyrite, calcite, and frequently gypsum in the coal beds. A great variety of coal is found in the West, ranging from lignite to anthracite. Most of the samples of Alaska coal listed were taken from outcrops or prospects, and range from refractory class 1 ash to ash of medium fusibility of class 2. The coals from Washington show all three classes of fusibility. The majority of the samples, however, come in class 1 and class 2. These coals have a high ash content, but in many the ash is refractory. Oregon and California contain little coal. The coals tested from Colorado and New Mexico range from refractory class 1 ash to easily fusible class 3 ash, the majority of the samples tested coming in class 1 and class 2. Many of the coals from Utah showed ash of comparatively low fusibility, in the upper part of class 3; a considerable number of samples gave ash of medium fusibility, in class 2. A few samples gave refractory class 1 ash. The lignites tested, from North Dakota, South Dakota, and Montana, have ash of rather low fusibility, the majority of the samples coming in class 3 or the lower part of class 2. The sub-bituminous coals tested from Montana and Wyoming also gave ash of rather low fusibility, most of the samples coming in class 3 and the lower part of class 2.

*The laboratory fusibility tests were made by A. E. Hall, V. C. Allison, W. A. Selvig, C. R. Locke, C. S. Purcell, W. C. Ratliff, O. C. Brown, W. F. Holbrook, and A. M. Ondrejco, all of the chemical laboratory of the Bureau of Mines.

SOAPSTONE FROM CANADA

Canada is expected in time not only to fill its own demand for soapstone but to export considerable amounts of it. A concern known as the Wabigoon Soapstone Company, Ltd., with a capital of $500,000, which will mine soapstone in the Wabigoon district about 200 miles northwest of Fort William, was recently organized. The company is said to own one of the largest soapstone deposits known, and it is claimed to be the only deposit in Canada that can be worked commercially. Samples of the stone are reported to be of a greenish color, easily worked and of excellent quality. The development of the industry will be watched with interest by the pulp and paper companies who use this stone for lining kraft mill furnaces and pulp digesters.

NICKEL-BEARING STEELS ARE STANDARD

The use of nickel-steel in the automotive industry, has been so broad and experience with it has extended over such a long period, dating back to the infancy of the industry itself, that the compositions used have become well standardized both by users and steel manufacturers. Specifications are published, both by the Society of Automotive Engineers and by the American Society for Testing Materials, covering grades of nickel-bearing steels used in the automotive industry.

In consequence, nickel steels are readily secured even on short notice, as they are produced by all alloy steel mills who consider the 3½% nickel and low chrome-nickel steels as standard heats. They are carried as standard stock by many of the steel warehouses and large drop forge companies. The ease with which these standard steels may be secured has often prevented serious tying up of large production. Through long experience, the steel makers are more familiar with the technique required to produce a high quality of nickel alloy than of any other alloy steels. This, of course, guarantees uniformity of product and freedom from trouble both in shop fabrication as well as in the finished product.

Fundamentals of Transmission of Power by Belting

Relative Tension of Tight and Loose Side of Belt—Adhesion of Belt to Pulley—Pulley Grip a Dominant Factor of Transmission—Purpose of Belt Dressings

By LOUIS W. ARNY, Secretary, Leather Belting Exchange

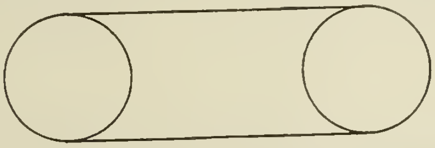
IN THE ideal belt drive, wherein the belt runs horizontally, pulling on the bottom, and in the modifications of it driving at an angle, certainly as much as 45 deg., and perhaps more, the belt still pulling on the bottom, we have a very favorable illustration of the value of elasticity in the belt. Where the belt is put on the pulleys under the usual tension of, say, 288 lbs., or thereabouts, when the belt is in a state of rest, the tension is fairly divided between the two strands of the belt (as illustrated in Fig. 1), if the shafts, or either one of them, are free to revolve. In the case of a belt of ordinary size, put on with belt clamps, the stress occasioned by the clamps usually is sufficient to revolve either one of the shafts to the extent of producing an equilibrium between the two strands of the belt, and the total tension on the belt is divided approximately evenly between the two strands. In the case of a very large belt, say a heavy main driver, over an engine and a long and heavy countershaft, this might not be exactly true, because it may be impossible to supply sufficient strain by the clamps to either slip the belt or to turn either shaft, so that the full strain of the clamps is not communicated to the other strand of the belt, and the tensions may be different. Ordinarily, though, in the case of smaller belts, the tension on the two strands of the belt in a state of rest is practically the same.

Effect of Motion

When the motion is applied, if the belt be of leather, the tensions probably will be slightly changed, even before the load is applied, the tension on the bottom side increasing slightly, and the tension on the top side decreasing slightly, but when a sufficient load is applied there gradually occurs a complete change, the bottom side becoming more taut, and the top side increasing in length and becoming loose and dropping considerably from a straight line drawn across the face of the two pulleys. Apparently, as in Fig. 2, the tension which existed in this top strand in a state of rest, has disappeared, or nearly so, and its total tension probably is not any more than that occasioned by its own weight. The tension on the bottom strand, however, has been increased by the application of the load, and whatever the load may be, it is being carried by this bottom strand. The carrying of this load by the bottom strand is dependent, therefore, upon the adhesion of the belt to the pulley, because there no longer is a tension on the top side to hold the belt in place. The belt is appreciably longer than it was when standing, and without this quality of adhesion, or pulley grip, it simply would slide around the pulleys, and the tension on the bottom ply would be lost.

Grip of the Belt

With a good leather belt this tension, however, is not lost, because the pulley grip is of sufficient intensity that the belt does not slide around the pulleys. It is obvious, then, that pulley grip is a dominant factor of transmission, and it must be remembered that this particular pulley grip of which we are talking, that is, the ability of the belt to hold firmly, or to stick tightly, to the pulley of its own accord, is a feature of the leather belt only, and that other types of belting do not possess it intrinsically. In belts which do not possess a natural pulley grip as described, it becomes necessary to supply something that will become its substitute, at least to an extent, and hence the use of sticky belt dressings, and the maintenance of a high tension on the top side. Some form of pulley adhesion may be supplied to them for a time by the application of "dope," but any advantage which they may acquire from such application is only temporary. Those belts which do not possess the elasticity of the leather belt, and hence will not pull out, or elongate, on the top side under a load, cannot rid themselves of their tension, or back pressure on that side.



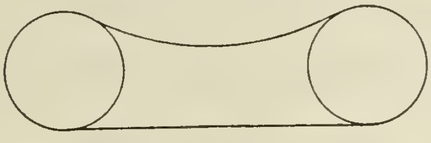


Fig. 1.—Top: tension evenly divided. Fig. 2.—Lower: tension on bottom portion due to load.

Power Transmitted

The power transmitted by any belt is the difference between the tensions of the top and bottom strands. From the total tension of the bottom side must be substracted the total tension of the top side. If, to prevent the belt from slipping, it be necessary that the original slow running tension on the top side shall be maintained, this must be deducted from the tension on the bottom side to secure the effective pull. This tension on the top side becomes a back pressure which the tension of the bottom side must overcome, and the maintenance of this tension, then, becomes a part of the cost of transmitting the load by this belt. If the same load can be transmitted by another belt without maintaining this tension on the top side, it is evident that it will transmit a larger load, or will transmit the same load at a less expense. Therefore, the belt whose pulley grip is sufficient to carry its load without slipping excessively, and which has sufficient elasticity to elongate on the top side to an extent to cancel the tension of that side, will operate more favorably, and more efficiently, than the belt whose adhesion to the pulley must be maintained by a continuance of the tension on the top side.

The factors of economical and efficient power transmission by belting, therefore, are pully grip and elasticity, and any belt to operate efficiently must possess both these qualities. This, then, becomes a measure of belt efficiency. Those belts which possess both of these qualities are efficient belts, and those which do not possess them both are inefficient. These points constitute the fundamental difference between leather and other types of belts. The grain, or hair, side of leather, properly prepared, makes a natural suction contact with the pulley which cannot be duplicated artificially in other materials. Many belts fundamentally are fabric, and fabric in any form is incapable of making this suction contact with the pulley, and is notably deficient in elasticity as compared with leather.

The advantages of elasticity in the belt as above described, are entirely separate and distinct from that other advantage of the increased pulley contact which is a result of the elongation of the top side of the belt. Pulley contact is one of the important factors of power transmission, and hence the more of the arc of the pulley that is covered by the belt, the more will be the power transmission; and the longer and looser the top strand of the belt may be, the more of the arc of the pulley will be covered. The value of pulley contact as a factor is, at least, in proportion to the degrees of arc of contact.

Combustion Enginee

THE COMBUSTION ENGINEERING CORPORATION, LTD.

Announces

A Complete Canadian Service

in the Combustion Field

Combustion Engineering Corporation, Ltd., of Canada, has acquired the sole manufacturing and sales rights in Canada for the following companies:

Combustion Engineering Corporation of New York
The Green Engineering Company of Chicago
Underfeed Stoker Company, Ltd., London, Eng.
Lopulco Systems, Inc., New York
Custodis Canadian Chimney Company, Limited

The equipment handled represents all types of mechanical stokers, pulverized fuel burning systems, ash conveyors, ash hoppers, air heaters, economizers, soot blowers, induced and forced draft fans, chimneys and recording instruments.

A research department with a complete engineering staff has been established. We solicit your inquiries.

Combustion Engineering Corporation, Ltd.

MR. A. J. T. TAYLOR, *Managing Director* MR. JOHN T. FARMER, *Chief Engineer*

Main Office: TORONTO

Montreal Winnipeg Vancouver

ng Corporation, Ltd.

A RESEARCH DEPARTMENT

has been established which has the benefit of the advice of such nationally known engineers as

JOHN VAN BRUNT, Chief Engineer, Combustion Engineering Corp.

HENRY KREISINGER, Research Engineer, formerly of United States Bureau of Mines.

JOHN E. BELL, Consulting Engineer, Research and Design.

T. A. MARSH, Chief Engineer, Green Engineering Co.

SAMUEL McEWEN, Chief Engineer, Underfeed Stoker Co., Ltd.

J. BEUZIT, Chief Engineer, Société Anonyme des Foyers Automatiques.

Power Plant
EQUIPMENT HANDLED

Green Chain-Grate Stokers
Green Ash Hoppers
Custodis Chimneys
Lopulco Pulverized Fuel Systems
Coxe Stokers
Air Heaters
Combusco Water Seal Ash Conveyor
Frederick Multiple Retort Stokers
Type E Stokers
Type D Stokers
Type K Stokers
Self Contained Stoker

Combustion Problems and Furnace Design

Experimental Research and Co-operation of Mechanical Engineer Necessary for Looking Into Combustion and Furnace Problems With a View to Developing the Soft Coal Industry

By PROFESSOR CHARLES A. ROBB, B.Sc., S.M.

A VERY interesting lecture was given by Professor Robb before a general meeting of the Alberta Association of Professional Engineers on January 6th at Lethbridge. This was in response to a request by their council who decided to have a series of papers presented to promote discussion and encourage the co-operation among the members of the association upon many of the problems that demanded their attention.

Professor Robb started his lecture by referring to the economics of research, pointing out that Faraday's discovery of the law of the electric dynamo in 1813, for which the apparatus cost less than five pounds, has made possible the whole electrical industry in which England alone had invested, in 1917, £600,000,000, and the United States in 1920 had invested no less than four billion dollars.

Continuing, he said that Newcomen's Atmospheric Engine of 1705, Watt's condensor of 1763, Watt's rotative type engine of 1781 and his double-acting engine of 1782, paved the way for the application of power to the development of industry, and revolutionized the whole economic structure of England. Out of this grew the demand for machinery to replace manual labor; the capital to secure the machinery; the great shops in which to make the machinery, and the grouping of workers in these shops. This sequence gave rise to our modern system of finance and the organization of labor.

The discoveries of Pasteur gave to France in five years, sufficient savings to pay the whole debt caused by the Franco-Prussian war. It would be interesting to know what percentage of the savings effected by research is actually reserved for further research work.

Alberta's Natural Market

A typical problem for the mechanical engineer is that of combustion and furnace design. We have in Alberta vast quantities of coal and in great variety. Canada has a great demand for fuel. The Canadian sources of supply are limited to the Maritime Provinces and the West. Middle Canada must therefore draw from the East, the West, or import coal from the United States, and the latter is becoming increasingly difficult. Alberta has therefore in Canada a natural market for her coal, and combined efforts have established a firm hold on the Winnipeg market. Credit is due to our Trade Commissioner, Mr. Stutchbury and his assistant Mr. Pratt, who have been very active in demonstrating the virtues and characteristics of Alberta coal.

In 1920 a series of tests were carried out at the Provincial Government of Manitoba plant in Winnipeg, and it was shown that Alberta had coal which could be laid down at Winnipeg in competition with United States coal, both as to quality and price.

Engineers who are coal consumers, choose from the coals available, the one best suited to the furnace of their steam boiler, as to variety, size and the method of firing. Our coals range in quality from the best grades of bituminous, to that of comparatively high moisture, and high volatile gases, or so-called domestic coals. Most of the latter are mined during the winter months and the proportion of slack is very high. A few years ago this slack was considered a waste product and was placed on the dump. Furnaces and stokers have been devised which handle the slack successfully and real economies have resulted in their use. This economy is very far reaching, in that the coal operator gets a reasonable price for the slack, and the operative engineer gets his coal for half, or less of the cost of nut coal and with approximately the same boiler capacity and efficiency.

No Difficulty in Storage

Every ton of the sub-bituminous coal burned locally makes the equivalent in bituminous coal available for export, and with the latter, the problem of storage through the summer months presents no difficulty, whilst with our present knowledge, the tendency of the "high moisture" coal to slack, or crumble, makes storage difficult and expensive.

The export of the bituminous coal insures a more equitable basis for freight and tends to stabilize the whole industry, leaving the domestic market to be served by the higher moisture coals.

The problem for the mechanical engineer is, therefore, to devise improved means for burning the domestic coal, that is to say, improve the furnaces and methods of firing. Having done that, they must encourage the use of boiler furnaces best suited to the local coals. Broadly speaking this calls for a furnace with ample combustion space to take advantage of the high percentage of volatile constituents, and to overcome the effect of the moisture. Some progress has been made, and this field should prove very profitable.

In 1914 a special furnace, supplied by Babcock & Wilcox, was installed at the University of Alberta to permit the use of slack coal. This gives a satisfactory steam for "Dollar" economy, and the current annual saving amounts to approximately $20,000.00 or 50 per cent. The plant consists of four units of which three are equipped with stokers, and the remaining furnace, which is hand-fired, is designed on liberal lines for the high moisture coal. The heating surface is 2,197 sq. ft. per unit and the grate area 60 sq. ft. for the chain grate stokers and 44 sq. ft. for the Dutch oven, hand-fired furnace. In all units the boiler is placed well above the grate and in the stoker furnaces, a heavy arch is provided to assist in the ignition of the green coal.

It has been found that the high-moisture coals will not ignite properly on the standard chain grate stokers as designed for bituminous coal, and before the furnaces were rearranged the practice was to mix in a portion of bituminous coal which proved rather expensive.

Burning Slack Once Wasted

Other plants in the Province, including the municipal plants at Edmonton and Calgary, now burn slack coal that formerly was wasted. The annual reclamation value from this source must now be little short of half a million dollars, while the saving in coal cost to the plants is large.

Present conditions leave us with a moderate efficiency for the boiler and furnace and the specific problem covers a study of the furnace to establish suitable proportions, arrangement of arches, draft for various thicknesses of fire, etc., and special characteristics applying to stokers.

A comprehensive programme if developed in co-operation with the superintendents of the larger plants in the Province would lead to the accumulation of data covering the experimental work already accomplished, and co-ordinating efforts in the future. Broad outlines could then be established for the guidance of engineers in the design of furnaces for steam boilers and higher efficiencies should then be obtained.

A further point is that authoritative data covering furnace design should help to rectify the confirmed practice of installing furnaces suitable for bituminous coals only, to serve large steam boil-

(Continued on page 36)

Fitting of Keys in Crossheads and Flywheels

Operation That Requires Particular Skill—Sharp Corners Should Be Avoided—Parts Must be Accurately Fitted Before Driving Keys—Select Right Position for Keyway

A CHAIN is no stronger than its weakest link and in an engine there are so many "links" upon which the safety of the whole structure depends that considerable care must be exercised to see that all parts are in as good condition as circumstances will permit. Engines should be overhauled from time to time and this, very often, calls for a disconnecting of several parts. At times it may be necessary to replace old and worn parts with new. In such replacement a great deal of attention must be paid to securing correct fits or mating of the new parts with the old. In particular, we have in mind the fitting of the piston rod into the crosshead which, when these two are keyed or gibbed together, is a job calling for no small degree of skill.

Work for Skilled Mechanic

Attention need hardly be called to the desirability of obtaining the services of a first class mechanic skilled in the fitting up of engines to do such work. Such men are not always available, however, and the owner may have to be contented with a less skilled workman. In such cases the owner will naturally be interested in knowing how the work should be done so that he may give instructions to the mechanic he employs. Even with skilled hands to do the work the owner will naturally have some interest in the reasons for the steps that are taken.

The more usual construction that is found in this type of cross-head and piston rod joint is the one in which the end of the rod is tapered, although the straight cylindrical end is sometimes used. These two variations in the general construction are illustrated in Figs. 1 and 2. The end of the rod, where it fits into the crosshead, is sometimes relieved or undercut over a length slightly greater than that taken up by the keyway. This is illustrated in Fig. 1. The cylindrical end is also made with the outer or tip section of a slightly smaller diameter than the inner section, the part between the two being undercut. It should be borne in mind, however, that any reduction in the diameter of the rod will naturally weaken it and undercutting should not be done without due consideration of this effect. Furthermore, sudden changes in diameter with sharp corners should always be avoided because very severe stresses may be produced thereby. The end of the rod should also be rounded off as shown to avoid possible cutting when it is pulled into the crosshead.

Fitting the Tapered End

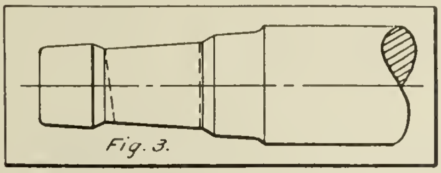

Fig. 3—Relieving middle portion.

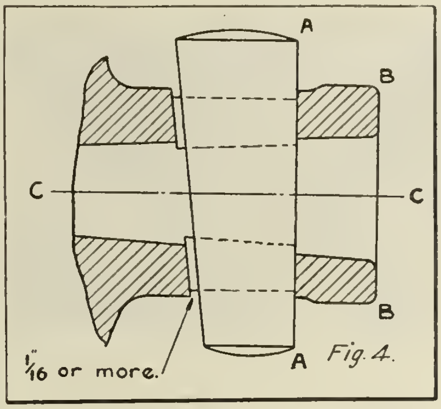

Fig. 4—Arrangement of tapered key.

A description will be given of the method of fitting the tapered end and from this it will not be difficult to see what treatment should be given the cylindrical end. The first step is to fit the tapered end of the rod into the hole in the crosshead so that the two parts will bear evenly and fully on the surfaces which touch each other and so that, when pushed together by hand, there will be a slight space between the end of the crosshead boss and the shoulder on the rod.

This space is for the "draw" and will be taken up when the key is driven in, thereby providing a snug, tightly-fitting joint. The amount allowed for this "draw" will vary with the size of the rod and the degree of taper. On large diameter rods not so much would be allowed as on small rods. With a rod diameter of 2½ in. about 1/16 in. would be correct. If the rod has a cylindrical end, the two parts should go together with what a machinist terms a "push fit."

The tapered end of the rod should be lightly smeared with Prussian blue and the two parts pushed together by hand and then given a slight turning or twisting motion. When the parts are separated those surfaces which had the closest fit will have the blue fairly well rubbed off and should be carefully filed down with a fine cut file until a neat fit is obtained over the entire length of the taper. It will be noted that no small degree of skill is called for in this fitting as a full bearing must be secured while keeping the diameters such that the proper "draw" is provided.

Proper Arrangement

After this fit is secured the next step is to obtain the proper relation between the key and the keyway or slot in the crosshead. This is shown in Fig. 4. The key, in this instance, has been shown with the tapered edge facing inward. The arrangement may be the reverse from this but, whichever it may be, it is desirable that the straight edge A-A be at right angles to the axis C-C. If the face B-B of the crosshead has been turned square with the bore this condition of the key may be inserted by making the edges A-A and B-B parallel. Sometimes the key is tapered on both edges. In such a case a vertical dividing line or axis may be scribed on it and this line may then be used as a reference to obtain the right angle condition. We might add that it is not absolutely essential that the key and the axis of the bore be at an exact right angle. There may be some deviation from this but whatever it is should be carefully noted.

Position of Keyway

The position of the keyway in the rod should be such that the relation shown in Fig. 1 will be obtained when the shoulder on the rod is brought up firmly against the crosshead. Note that it is well to provide some clearance at the front end of the keyway in the rod. It will be sufficient to make this 1/32 in.

While the position of the keyway in the rod may be obtained with comparative ease it must also be borne in mind that the tapered side of this keyway

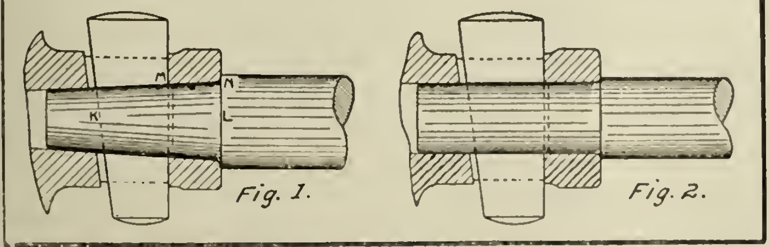

Fig. 1—Showing a tapered fit. Fig. 2—Parallel fit.

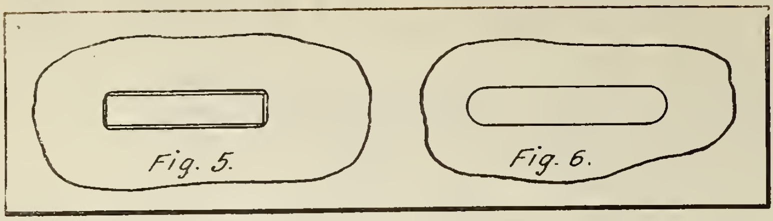

Fig. 5—Keyway with square corners. Fig. 6—Keyway with round ends, minimizes chance of breakage.

must make the proper angle with the axis of the rod. The key should be placed in the slot and, while it is bearing against the tapered side, its angularity with the axis of the rod should be measured. This angularity should be the same as that given the key when placed in the crosshead and brought to bear against the straight, non-tapered side. If this is not done, the key, when the parts are assembled, will not have a full bearing over its entire length and severe local stresses may be set up.

Making the Joint

The joint may now be assembled, the key placed in position and then driven in until the shoulder on the rod is brought up firmly against the end of the crosshead. By this method of fitting, a tight joint is made by pulling the tapered rod rigidly into the crosshead. The holding stresses will be a hoop tension or tensile stress in the metal surrounding the rod with a corresponding compression in the rod itself. These two stresses produce a pressure on the bearing surfaces which thereby set up a large frictional force to hold the joint together. In addition there is a tensile strength lengthwise in the rod between points K and L and compression in the crosshead between points M and N. (See Fig. 1.) Of course when the engine is operating there will be alternate compressing and pulling of the cast metal beyond the point M, but the crosshead has been designed by the maker to carry this stress, provided, of course that no accident occurs. This is a tensile stress that can be predetermined, whereas the tensile stress that can be set up by an improperly fitted key can very readily become severe enough to wreck the best of designs. The illustration shows a crosshead that was broken by an improperly fitted key.

There are a few points regarding this fitting of the key in the crosshead that require particular care. If a rectangular key is used the corners should be relieved because it is difficult to obtain a perfectly square cornered hole in the crosshead. A key with square corners produces the effect shown in Fig. 5, which condition cannot help but set up stresses tending to shorten the life of the crosshead. An excellent way to avoid any such trouble is to make the key with full rounded edges as shown in Fig. 6. Of course this requires possibly more time to fit than a rectangular key but the stresses are more equally distributed. If a rectangular key cannot be avoided it should have the corners relieved.

Disconnecting the Rod

It is not always easy to separate a rod and crosshead when they have been drawn firmly together on a taper joint. For such work a "driving out" set of keys is very helpful. This set is composed of three specially formed pieces which are shown in Fig. 7, assembled in place and ready for use. By striking on the center wedge B, the joint may very readily be eased up.

Fitting Shaft Keys

Some mention might also be made of the keying of wheels and pulleys to shafts. The function of a key used for this purpose is to prevent turning between the wheel and the shaft, endwise motion or sliding usually being prevented by set screws or by the compressing of a split hub on the shaft. For this reason the key should be a close fit on the sides but should have a clearance at the top. If this clearance is not provided, the load, when the hub bolts are tightened up, will be concentrated over the key, and the stresses tending to break the hub will be very much greater than if the load were equally distributed over the shaft. The illustration herewith shows a flywheel hub that was broken in this manner. The key had first been driven into place without allowing for the proper clearance and the hub bolts were then heated, put into place and pulled up tight. When the bolts cooled they of course exerted an intense clamping effect on the hub. The load was localized, however, over the key and, although failure did not take place immediately, the hub, no longer able to withstand the severe stress, broke, as shown, about a month later.

EFFECT OF NICKEL ON STEEL

(Continued from page 22)

gineer and the metallurgist, who selects the proper analysis and heat treatment, a wide range of possible physical properties to meet successfully almost every engineering requirement of tensile strength, elastic limit, ductility, hardness, and resistance to abrasion, shock and fatigue. In this condition we see it used in important forgings, axle shafts, gears, cam-shafts, piston pins, etc.

Nickel steels are an almost indispensable material for case-hardening or carburizing. The case-hardening process is used to secure an extremely hard surface, or case, combined with a tough center or core. We see from the effects of nickel on steel, noted above, that it naturally tends to fulfill this condition.

COMBUSTION PROBLEMS AND FURNACE DESIGN

(Continued from page 34)

ers, and which gives neither good boiler efficiency nor capacity.

Stoker manufacturers are recognizing the demand for more liberal combustion space as evidenced by their action at a convention last year in settling upon certain dimensions for various stokers. Experimental work has been carried out on lignite coals by the manufacturers of the B. & W. Jones, Green and Allan stokers. During the past month, word also came of results on the turbine stoker.

Investigations with a view to the solution of such problems is called Industrial Research. There is established in the province a Provincial Research Council, which exists as a department of the University with a staff of research engineers. In the organization of the Provincial Government, the work of the Research Council is attached to the Department of the Provincial secretary.

With regard to fuels, the programme of the council for the future includes "Screening and Storage," "House-heating" and "Furnace-tests" on coals. Boiler trials have been carried out on all the large samples of coal, also one on mixed coal. Fourteen trials in all have been made during the year. An experimental carbonizer for lignites is in operation, also a briquetting machine.

Precaution Necessary With Oxygen

ALTHOUGH we think it is generally understood by engineers, that compressed oxygen must never be allowed to come into contact with mineral oil, they must not at the same time overlook the fact that it is equally dangerous to allow this gas to come into contact with any form of lubricating oil or even grease. It was due to this cause that one or two disastrous explosions have recently occurred, which were of such an appalling nature, that it is advisable for those who have any dealings with compressed oxygen to take this timely warning.

In one case, a 100 H.P. gas engine, which was usually started with compressed air raised to a pressure of eight atmospheres, was about to be started up. By some unfortunate misunderstanding or mishap in the mechanism, the cylinder of the gas engine was charged with compressed oxygen that had been raised to a pressure of seven and a half atmospheres. The moment the engine started to move, a violent explosion occurred in the cylinder killing the engineer and his mechanic, who were both standing nearby, and also seriously injuring several other workmen who were working some distance away.

In another case, an engineer who had charge of a refrigerating plant, had to charge up his system with ammonia. On account of the similarity in appearance, he took a bottle of oxygen by mistake, and whilst he was charging his machine, it exploded blowing the machine to pieces and instantly killing the engineer.

If engineers would only realize the danger of bringing matter of an oxidizable nature in contact with compressed oxygen, it would promote greater safety in plants and tend to reduce the liability of disaster. Manufacturers of the gas, who are aware of this condition, take the greatest conceivable care to insure that the gas is not contaminated.

It is interesting to note in following the history of oxygen compression, that accidents have occurred with some of our most thoughtful and experienced men, who would never have dreamed that such a small percentage of impurity could have had, or been the cause of such drastic consequences. In the case of oil, it is not merely the combustion of the oil itself that causes the trouble, but the metal parts of the apparatus burn freely as soon as they become sufficiently heated by the ignition of the oil or grease, and the consequences may transcend all imagination. The only lubrication that is used in an oxygen compressor is pure water, except in a few isolated cases where a little soap is dissolved in the water. In such cases, which are usually to meet a special condition, the mixture of soapy water is thoroughly analyzed to first insure that it contains no uncombined or unsaponified oil or grease, and furthermore, the packings that are used must be absolutely free from grease or graphite. If, therefore, such precautions are necessary in the manufacture of this gas, the same precaution is necessary in using it, and when a man talks with appropriate earnestness about the danger of allowing compressed oxygen to come into contact with oil or other combustible organic material, it is easy for those who are unenlightened or uninitiated to believe that he is inspired by unreasonable precaution or timidity, but this is not the case.

Lignite Coal

REVIVED interest has lately been shown in respect to the development of some of the larger deposits of lignite throughout the Dominion. These deposits in many cases are in the form of thick seams of easy access, which could be cheaply worked. The physical properties, however, such as the high percentage of water, low calorific value, disintegration in handling and storing, and lacking in coking properties tend to depreciate its value as a commercial heat-giving product. Its character, we are afraid, has fallen into even further disrepute on account of the poor success that has been experienced in attempts to successfully burn this low-grade fuel in an ordinary boiler furnace. Haphazard methods are of no use whatever, and if these wonderful lignite fields are to be developed, the situation should be grappled with in a proper scientific manner.

A very promising field offers itself wherein this class of fuel could be used in the pulverized form, and some very encouraging results were recently obtained from experiments conducted upon Texas lignites. One of the difficulties in this system, is retaining, during the process of carbonization, sufficient volatile matter to insure continuous burning. The low-temperature carbonization of lignite is also a process that will open up new avenues for research. This is comparatively a new process which should prove to be most interesting both from a commercial and scientific standpoint. It is a case where the chemist must join hands with the engineer, and with their united efforts we will know that the subject is being pursued to its ultimate end. Experiments have recently been conducted in England upon these lines, which have shown it possible to considerably enhance the calorific value of low-grade coals, and at the same time recover various useful by-products in the process. The upgrading of this type of fuel may also be effected by the utilization of the waste gases generated in the process, and which helps to very materially cheapen the cost of operation.

It would therefore seem that there are great possibilities for the future development of some system whereby lignites could be utilized for the generation of power on a large scale and there is no doubt that whatever obstacles that have been met with in the past would be eliminated one by one.

Our Question Box

Question.—If a large volume of water which was stored on a hill top was released and allowed to run down the hill and up the side of a hill facing it, would it reach the same height as the point from which it was released?—H.C.F.

Answer.—We understand this is the question H.C.F. wishes to ask, and we had better explain in the first place Torricelli's Theorem. "The velocity with which a liquid issues from a small orifice in the side or bottom of a vessel is equal to the velocity which would be acquired by a body in falling from the level of the surface of the liquid, to the level of the aperture." This applies equally as much to water flowing down a hill side since the water although flowing over the surface of the ground is actually "falling," but it is being subject to a greater surface resistance by falling in this manner, than it would by falling vertically down through the atmosphere. If water could be run down a chute that was so well lubricated that it was without friction, then the water would rise on the opposite hillside to the corresponding level of water from which it had originally started from. To explain this by way of formula, we would point out that the velocity of the water at the lowermost part of the valley or at the point where it leaves the orifice in the tank is proportion to the square root of the depth, providing there is no friction or resistance. To double the velocity we require to make the depth or height four times as great. If, therefore, H be the depth of the orifice or the vertical, height of the hill, V the velocity of the liquid, and G equals gravity (32), then

$V^2 = 2\,GH$ and $V = \sqrt{2GH}$

Question.—In babbitting a solid journal there is difficulty in removing the shaft to cut the oil grooves. What is a good method to overcome this trouble?—G.E.P., Edmonton.

Answer.—We are afraid that whatever method is adopted, the result would be that the ends of the oil groove are left open, thereby allowing the oil full exit. It may be posible, however, that these ends could be plugged up and we would suggest that a piece of clean, half-round split pin wire be bent around the shaft pin spirally with the flat side around this wire, which, after being left to cool down, will contract sufficiently to allow the wire to be withdrawn, leaving the half-round impression in the bearing metal. It is possible to burn a small portion of metal over the ends of the groove to prevent the oil from running away.

Question.—Could you tell me the name of a good book on babbitting?

Answer.—We do not know of any technical book on the market that makes a specialty of babbitting. Perhaps, however, if you get in touch with some of the big American publishing houses, they might be able to advise you of a book that touches upon the subject sufficient to meet your needs.

Question.—I have a hand force pump fitted in my house which is situated about 160 feet away from the well. It has a lift of 60 ft. and gives me a lot of trouble to get the water, and I would like to know the best thing to do.—F. B. Foleyet.

Answer.—We are afraid F. B. has made some mistake in his measurement. If his pump is an ordinary suction pump, as we should imagine it was by the description he gives, then he cannot possibly draw water from a depth of 60 ft. When a pump lifts water it withdraws the pressure of the atmosphere from the surface of the water inside the section-pipe, and the pressure of the atmosphere outside the suction pipe forces the water up until the pressure inside and outside become balanced. The distance the water is lifted is equal to the height of a column of water weighing 15 lbs. per square inch of area at the base which is theoretically about 34 feet. It is impossible in practice to have perfect tightness as some small leakages of air are sure to occur at the joints, valves or piston, and a perfect vacuum is never obtained.

The greatest distance that a pump will lift water is 28 feet, but even at this distance the pump is liable to lose its water if the barometer is standing very low. To prevent occasionally having a dry pump, the supply should never be drawn through a greater height than 25 feet, but as the efficiency of the pump varies, the suction pipe should be shortened up as much as possible and the maximum safe distance that should be made is 15 feet to insure that the pump will work well and uniformly at all times and draw the proper quantity of water at each stroke. It will of course be understood that the quicker the speed of the pump the shorter the suction pipe will have to be made. If, therefore, F. B. will study the principle of the pump he will be in a better position to know how to act because his explanation was not made too clear in his letter to us.

The question of the inter-provincial acceptance of engineers' certificates granted by provinces outside the one in which an engineer may be residing is commented upon by R. N. Blackburn, chief inspector of steam boilers, in his annual report to the Department of Public Works.

Some suggestions for the working out of a practicable scheme were made by Mr. Blackburn at an interprovincial conference held at Winnipeg in 1918, but, owing to pressure of other work, the matter was left in abeyance.

Mr. Blackburn says:

"It may reasonably be supposed that an engineer who is qualified to operate a steam engine in one province is equally qualified to operate a similar engine in another province, and at first sight it would appear that there should be no difficulty in arranging for inter-provincial certificates. In practice, however, there are a number of difficulties to be provided for. For example, the standard of examinations varies very considerably in different provinces, and it would manifestly be an injustice to engineers in a province where the standard of examination is fairly high to admit engineers from other provinces where the standard of examination is low on an equal status with them. Again in some provinces there are a large number of engineers holding certificates which they have obtained without examination, and it would be obviously unfair to Saskatchewan engineers who have passed a fairly high standard of examination to admit men holding such certificates on an equal footing. Also the grading of certificates in respect of the capacity the steam plant which the holder of the certificate is authorized to operate varies very considerably in the different provinces. Finally, the province final certifi-

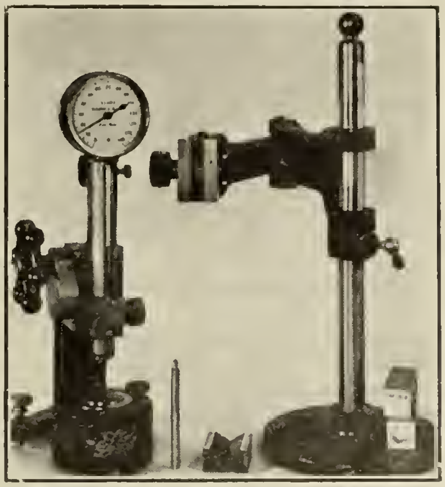
Progress in New Equipment

DIAL RECORDING SCLEROSCOPE

The scleroscope which has long been in general use for measuring the hardness of metals, is now provided with permanent indicating mechanism, a pointer hand and graduated dial. This feature is to be contrasted with the original model classified as Model C-1, in which the vertical graduated scale is used and against which the height of the rebound of the hammer indicating the hardness is read. The improved dial instrument is known as the "Model D Recorder," for here, instead of the indication being momentary, the hand remains fixed an indefinite length of time, or until the next test is made. The mechanism employed consists of the usual drop hammer. The function of this hammer is, by virtue of its accumulated energy of motion, to overcome the penetrative resistance of the metal under test. This absorbs more or less of its striking energy, which is always constant. That which is not absorbed, as most notable in the harder metals, remains available for reacting on, or rebounding the hammer itself, and which is proportional to the hardness of any metal.

Dial indicator attachment.

The hammer employed differs from the earlier models in that it is longer, heavier and drops and rebounds a comparatively shorter distance. The mechanism consists in the main of a sensitive one-way ball clutch and pilot sleeve, which normally holds the hammer at its upper starting position. When released, the pilot sleeve falls with the hammer, with the result that the slightest rebound, even though less than one thousandth part of an inch, is instantly fixed by the one-way clutch. Following this cycle, the clutch assembly is raised up to its starting position, carrying the hammer with it in its now superposed position, due to the percentage of rebound recorded. Simultaneously, the hammer arriving at its upper or starting position, engages and actuates a rack and pinion and hair spring dial mechanism, which in turn faithfully indicates the amount of rebound of the hammer and, therefore, the hardness of the specimen. The hardness values shown by this instrument agree faithfully with those shown on the vertical scale, or the older instrument, which is still popular and which the manufacturers shall list as heretofore, but which can be supplied at a somewhat lower cost.



Dial recording scleroscope.

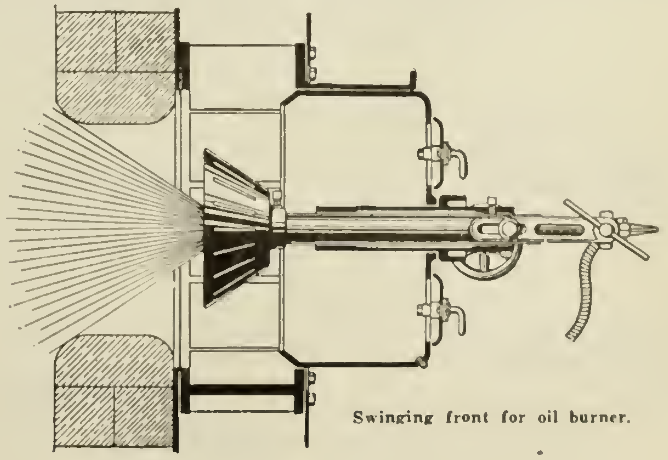
SWINGING FRONT FOR OIL BURNERS

Improvements have been made to the Bethlehem mechanical oil burning apparatus by incorporating a new swinging front which may be used with both natural and forced draft. This new front, says Marine Engineering, combines all the features of the regular burners, including the slotted cone, the nine-vane air register and hand ratchet adjustable pot air valve. Probably the greatest advantage claimed for the new front is that access to the furnace may be had without taking down the front. The front may be swung aside by simply moving two dogs and removing one lock pin. The front half of the pot swings open with the front itself, leaving the vanes of the air register locked, so that in the case of forced draft any one of a battery of furnaces may be opened without interfering with the draft in the others. Cone adjusting handles have also been added and a peep hole put in the slotted cone which lines up with a peep hole in the door so that the operator can observe the flame at the burner tip from in front of the furnace. Three Luckenbach ships which are being equipped with the largest Scotch marine boilers ever built are being fitted with this new type front—forty-eight furnaces in all.

SAFETY LOCKNUT

A new type of locknut has just been placed on the market. In this design of locknut it is not necessary to drill a hole through the bolt, as the nut proper has a slot cut across its outer face in which a clip is fitted to engage with the thread of the bolt. After the clip is in position the two pointed ends are closed around the thread. It is claimed that a grip is obtained that prevents turning of the nut, while no damage is done to the threads of the bolt. It is also stated that the nut cannot be removed from the bolt while clip is in place, without injury to the thread. It is further claimed that the nut can withstand vibration as well as twisting strains without signs of loosening. These nuts are furnished in all standard sizes up to ¾ in. and larger if desired. These nuts are made by the Specialty Manufacturing and Sales Co., Brooklyn, N. Y.

The safety engineer must be a social engineer. If he can invent and educate the "safety spirit" among the entire force from top to bottom, then the workmen and foremen will invent and demand and use more safety devices than he ever could think out and install by himself. He adds his personality to the going concern.



Swinging front for oil burner.

Operators Point of View

A USEFUL PIPE CHART

By W. F. Schaphorst.

We often want to know the velocity of flow through a pipe of given diameter, and, we want to know quickly. Or, we want to know the cubic feet of liquid or gas flowing through the pipe per minute, the gallons per minute, or the pounds of water per minute. All of these quantities are dependent, of course, upon the size of the pipe, and since pipe sizes vary, standard pipe not being exact in internal diameter and extra heavy pipe being different also, it is always necessary to search through tables and make lengthy calculations before arriving at the results. And then, after a result is arrived at one is not certain that the answer is correct.

Here is a chart that takes care of all of these matters in a decidedly simple way. The best way to explain the use of the chart is to give a problem. First, it will be observed that there are three sets of figures given in connection with the left hand column A. The left hand column of figures, marked "No. 1, standard," gives the actual internal diameter of standard pipe. This column shows, for example, that the internal diameter of a 1 in. standard pipe is somewhat greater than 1 in. The column of figures marked "2 exact," gives the exact diameter. Thus if we have a pipe the internal diameter of which is exactly 2 in. as used in the problem which is cited below, we have this column of figures. The right hand column of figures marked "3 extra heavy" gives the actual internal diameter of a 1 in. extra heavy pipe as less than 1 in.

For example, how much water is passing through a pipe, the internal diameter being exactly 2 in. and the velocity of the water being 2 ft. per second? Locate the 2 in column A over the word "exact" and from its point of intersection run a straight line through the 2 ft. per second in column C as shown by the dotted line. This straight line intersects column B. From the point of intersection in column B, run a straight line over to the similar point of column G, also as shown by the dotted line. The intersection of this perfectly horizontal line from column B to column G gives answers simultaneously in three columns —columns D. E and F. It shows that: 2.6 cu. ft. per minute are flowing through the pipe. (The correct amount is 2.615 cu. ft.) A trifle over 19 gallons per minute are flowing through the pipe. (The correct amount is 19.58 gal.) About 165 pounds of water per minute are flowing through the pipe. (The correct amount is 163 lb.)

This shows that the chart is accurate enough for all practical purposes.

It is evident, now, on studying the chart, that if the pipe were a two inch "standard" pipe instead of exactly 2 inches, the horizontal line from column B to column G would be slightly lower and three quantities would be slightly greater. On the other hand it is evident that if a 2 inch extra heavy pipe were used instead of the 2 inch exact, the horizontal line from column B to column G would be raised slightly above its present position and the three quantities would therefore be slightly less.

At the same time it will be noted that this chart can be conveniently used as a conversion chart. For example, how many gallons in 2.6 cu. ft.? The dotted horizontal line already drawn shows that the answer is—slightly over 19 gallons, which is also equivalent to about 165 pounds of water. At the same time this chart gives a visual demonstration of the relationship of pipe sizes—standard, exact, and extra heavy. By using this chart one can quickly "read off" the correct internal diameter of a standard or extra heavy pipe. The range of this chart has been made great enough to take care of almost any problem dealing with water, the standard pipe sizes ranging from 1/8 in. to 15 in. and the velocities from 0.3 to 20 ft. per second. Should anybody prefer to use formulas rather than this chart either for solving the problem directly or for checking the result taken from the chart, here are the formulas on which the chart is based:

$$Q = 2.45\ d^2\ V$$

where Q = gal. per minute;

d = internal diameter inches;

V = velocity, ft. per second.

Cu. ft. per minute $= 0.327\ d^2\ V$

Lb. water per minute $= 20.4\ d^2\ V$

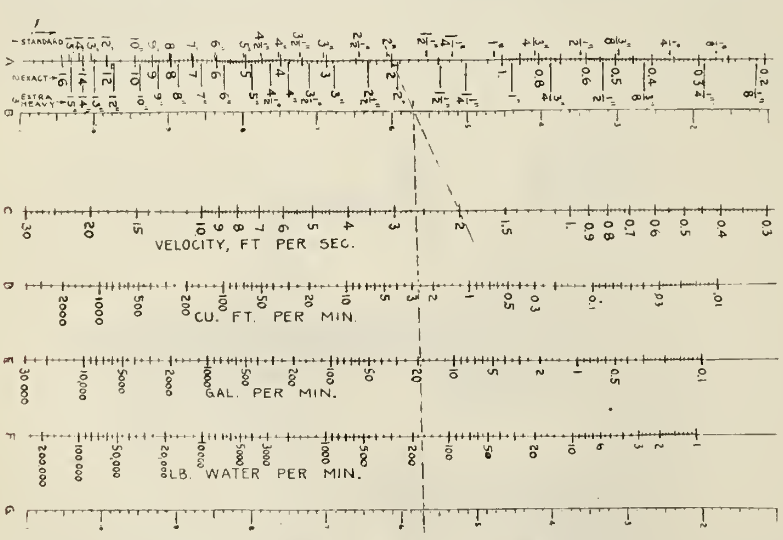


Chart for finding velocity of flow through pipes.

COMBUSTION OF SAWDUST

The burning of sawdust for boiler purposes is best accomplished by means of a simply-constructed "Dutch-oven" furnace, according to the United States Bureau of Mines. As a rule only one feed hole in the roof of the furnace is used, for sawdust is such an excellent fuel that it will produce a hot fire even when handled roughly and carelessly. Of course, with a single feeding hole in the top of the Dutch oven, the sawdust forms a cone on the grate surface. A cone is about the least effective form in which any fuel may be arranged on a grate for burning. The draft penetrates the bed of fuel at the points of least resistance, that is, at the shallowest parts; hence the air enters at an excessive rate around the edges of the cone while the largest part of the grade is effectually air-tight and consequently is "dead." This difficulty can be reduced or eliminated by different methods, which are described in Technical Paper 279, just issued by the bureau.

MR. CHAS. HETT DEAD

Mr. Chas. Hett, of the Boiler Repair and Grate Bar Co., died on Sunday evening, the 18th inst., in Toronto in his 69th year. He was salesman for the above company for about 33 years and was well known throughout the Dominion by engineers. His brother Adam Hett, is the president, and Oscar Hett, who is his nephew, the manager of the same concern.

Ottawa Car Manufacturing Co., have considerable work on hand at the present time, including fifty cars for Toronto Transportation, two cars for Moncton, N. B., and two cars for Oshawa Railway Co., Oshawa.

Electrical Section

Practical Electricity for Power Plant Engineer

By G. R. ARCHDEACON, A.M.I.E.E.

THERE are two distinct systems of winding armatures: one is called lap-winding, and the other is known as wave-winding; the prefix "lap" and "wave" describe the form taken by the winding in each case.

If at one end of the armature we connect a conductor to another conductor, which is separated from it by a distance approximately equal to the pole-pitch (the distance measured along the armature circumference, between the centre lines of two neighboring pole pieces) the E. M. F.'s in the two conductors will at every instant be added. The reason is that whilst one of these conductors is passing under cover of a north pole-piece, the other will be passing under cover of a south pole-piece, so that the two E. M. F's act in the same direction round the loop formed by these two conductors. (Fig. 1).

Such a loop forms a complete turn of the winding. For convenience in making the end connections between conductors, one of each pair of conductors forming a loop or turn of the winding, is placed at the top of a slot, and the other at the bottom. Usually the coils forming the top layers in a slot are given odd numbers to identify them, whilst those at the bottom of the slot are given even numbers. (Fig. 2).

Lap-Winding

For the sake of simplicity, we shall suppose each slot to contain only two conductors arranged one above the other. Let the slots be numbered consecutively and let us suppose that we start with the top conductor in slot 1 (Fig. 3). The top conductor in slot 1 is carried forward by an amount equal to the pole-pitch. It is there laid in the bottom of the slot. We thereby form a single turn of the winding. Now let the remaining end of the conductor at the bottom of this slot be bent backwards, so that it can meet the end of the top conductor in slot 2, which is bent forward and let the conductors be joined as on the other side of the core. Now the top conductor in slot 2 forms the beginning of the next loop or turn, it being carried forward again by the amount of the pole-pitch, and then bent backwards again to link up with the conductor in slot 3, etc. We will later observe that we obtain a succession of over-lapping loops or turns, hence the name lap-winding.

A closed-coil or re-entrant winding must always fulfill the condition, that the total resultant E. M. F. around the winding vanishes; otherwise there would be local currents circulating in the armature winding even when there was no connection to an external circuit.

Lap-winding is sometimes called multiple or parallel winding because of the fact that such a winding consists of as many circuits as there are field poles, and these circuits are connected in parallel between the brushes. The number of brushes required therefore equals the number of armature sections in parallel, and also equals the number of pole pieces.

A lap-winding can always be distinguished from a wave-winding from the appearance of the end connections. In the wave-winding, the front and back ends of the coils lead in opposite directions. With a lap-winding the front and back ends of the coils continue in the same direction round the armature.

Pitch of Winding

The distance between two sides of a coil measured in coil sides at the front or commutator end of the armature, is called the front pitch. The distance between two sides of a coil, measured in coil sides at the back end of the armature, is called the back pitch. The total winding pitch is equal to the algebraic sum of the front and back pitches. That is, in a lap-winding, the front and back pitches are of opposite directions on the armature, and the total pitch will therefore be the difference between them.

When a coil spans exactly the distance between the centres of adjacent field poles or a full pole pitch, it is said to be a full-pitch coil. In cases where a coil is less than a full pitch, it is said to be a "fractional pitch" or a "short-pitch" coil.

Fractional pitch windings are much used, because of the following advantages:

(1) They make it possible to have shorter end connections and therefore call for less copper.

(2) Armature reaction is reduced be-

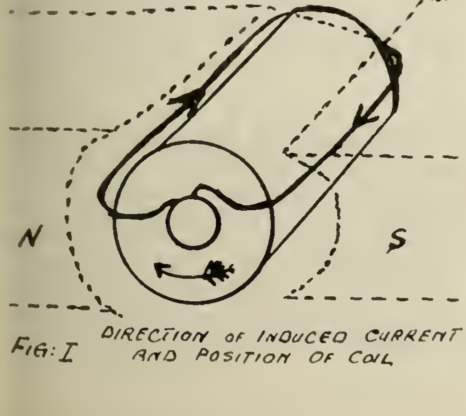

FIG: I DIRECTION OF INDUCED CURRENT AND POSITION OF COIL

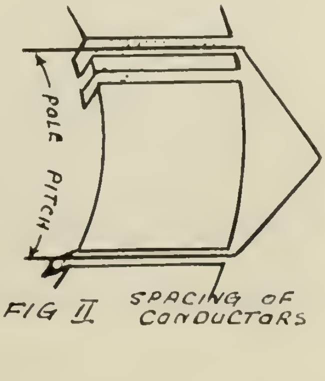

FIG II SPACING OF CONDUCTORS

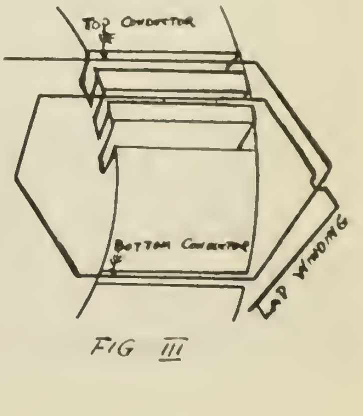

FIG III

cause the currents in the neutral zone flow partly in opposite directions and so neutralise each other.

Mr. Daniel H. Braymer of the "Electrical World" has developed a very concise formula on the selection of pitches for lap winding, which are given below:

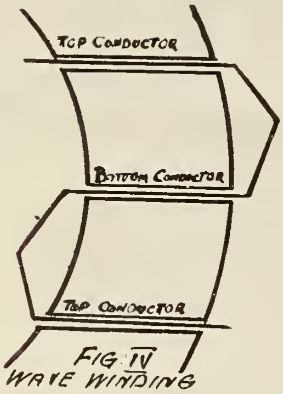

FIG IV
WAVE WINDING

Formulae for Lap Winding

(1) The front and back pitches (in winding spaces or coil sides) must both be odd numbers and differ by two or some multiple of two.

(2) The front and back pitches are of opposite sign (one positive and the other negative) since they are laid off in opposite directions on the armature.

(3) The winding pitch is equal to the algebraic sum of the front and back pitches. Suppose the front pitch be plus 9 and the back pitch be minus 7, the algebraic sum will be (9 — 7) = 2.

(4) The total number of armature conductors must be a multiple of the number of slots on the armature.

(5) The number of armature slots may be odd or even.

(6) The number of current collecting points or brushes on the commutator must equal the number of poles.

(7) The maximum E. M. F. between two consecutive coil sides (top and bottom) in the same slot, is equal to or a little less than the terminal voltage.

(8) The end of one coil is joined from the commutator to the start of another coil (usually the next) under the same pair of poles.

Mr. Braymer's formula is then as follows:

Front Pitch $= y_1 = \dfrac{N \pm b}{2p} \pm 2$

Back Pitch $= yk = \dfrac{N \pm b}{2p}$

Winding pitch = y = algebraic sum of y_1 and $y_2 = \pm 2$.

When N Number of coil sides of winding.
y Winding pitch or coil pitch.
y_1 Front pitch of winding element.
y_2 Back pitch of winding element.

It will have been made apparent that a lap-winding has two pitches, a forward pitch, and a smaller one in a backward direction. The coils will be alternately stepping forward with a long "stride" and stepping backwards with a short "stride."

Wave Winding

A wave winding possesses only one pitch, and that is in a forward direction all the time, these steps are in a zig-zag or wave-like form. These steps are made equal in order to render the winding symmetrical. This winding is frequently called a series winding or a two-circuit winding, because of the fact that half of the armature coils are connected in series, and the two halves are connected in parallel. The winding therefore only has two current paths in parallel between the brushes regardless of the number of poles. Only two sets of brushes are required with this type of winding, regardless of the number of pole-pieces on the machine. However, in cases where there is rather a high current value ,it is usual to fix additional brushes evenly spaced round the magnetic circuit.

The following is the formula for wave winding:

Winding pitch =

$$y = y_1 + y_2 = \frac{N \pm 2}{p}$$

Front pitch $= y_1$
Back pitch $= y_2$
Number of pairs of poles = p
Commutator pitch =

$$yk = \frac{y_1 + y_2}{2} = \frac{K \pm 1}{p}$$

Number of commutator bars =

$$K = \frac{N}{2} = p \times yk \pm 1$$

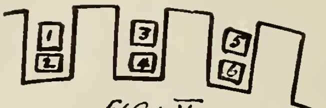

FIG: V
METHOD OF NUMBERING CONDUCTORS.

With an armature operating in a 4-pole field, either wave-winding or lap-winding may be used, but in a 2-pole field, only lap windings are used. In a 4-pole field, lap-winding is employed for heavy currents. In a 4-pole field, wave-winding is employed for light currents and high voltages. Lap-winding in a multipolar field, gives as many parallel paths for the current through the armature as there are poles. With the wave-winding, there are two circuits only, irrespective of the number of field poles.

Wave windings demand an odd number of segments on commutator.

Lap windings demand an even number of segments on commutator.

One of the advantages of wave winding in a multipolar field is that the combined effects of all the field magnets are added together so that any slight differences in pole strength does not cause sparking troubles through variations in the E. M. F. induced in each branch. To secure good commutation and eliminate heating and sparking troubles, all windings should be made symmetrical. This amongst other things means that there should not be more armature circuits in parallel than field poles. Where the number of armature circuits equals the number of poles, either the lap or wave windings may be used. The lap winding in such cases being most frequently chosen. The wave winding need only be considered in cases where the number of armature circuits will be less than the number of field poles.

Generally where changes in armature windings are necessary that call for a choice of windings, it is advisable to employ lap winding with as many circuits as there are poles, or a wave winding with two circuits.

In addition to the pitch of the coils on the armature there is also the commutator pitch to consider, the commutator pitch being the number of segments of the commutator spanned by the two ends of the coil. Suppose we number the segments of the commutator consecutively 1, 2, 3, 4, etc., and the commutator pitch is say 10, this would mean that one end of the coil was connected to segment number 1, the other end of the coil would miss 10 segments and would be connected to segment 11. The ends of the next coil would then be connected to segment number 12. In every case there would be 10 commutator segments intervening between the two ends of the coil.

EVERLASTING BOILERS

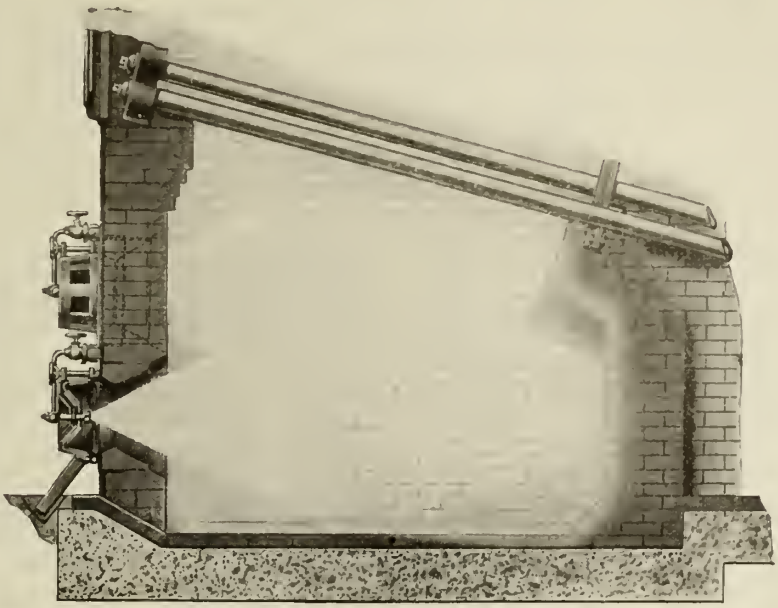
In some parts of England it is possible to find small steam boilers which were installed anything from fifty to one hundred years ago. These boilers are still at work and are kept at work more for sentimental reasons than because of their high efficiency. They provide, however, active witness to the excellence of British engineering. A short time ago a leading British boiler expert had the curiosity to subject two old iron boilers, probably about 60 years old, to careful tests. He found that the old iron stood up astonishingly well under heavy hydraulic pressure, and he noted particularly that the slight cracks which had been formed round the rivet holes in the original punching had not extended during the working life of the boilers. Thus he proved that the old kind of iron used in these British boilers was hardly surpassed by the material employed in the finest of up-to-date plants.

Defective elevator motor is the cause of a $2,000,000 fire. Three nine-storey buildings owned and operated by the Omaha Packing Co., Omaha, Neb., were burned to the ground by faulty equipment.

Montreal.—Two additional vessels are being built in England for Montreal Light, Heat & Power Co., owners of Keystone Transports, Limited. The latter are not interested in the investigation of the so-called shipping rate combine, as the whole of their tonnage is required for the transportation of coal for their owners.

BABCOCK & WILCOX

OIL BURNING EQUIPMENT



Babcock & Wilcox furnace for burning oil fuel only

The merits of oil as a fuel for steam generation, in places where its cost compares favorably with coal or wood, are, briefly, the following:—

1. An increase in boiler efficiency, owing to the clean condition in which the boiler heating surface can be maintained, and the completeness of combustion obtainable with a good system of oil firing.
2. A constant and equal distribution of heat in the furnace, and, as there are no fire doors to be opened, the cooling effect of a large volume of air passing over the furnace is avoided.
3. A reduction in the cost of handling the fuel, as this can be done by a pump; and a large reduction in manual labor, the firemen not being required as they would be for ordinary fuels. One man can regulate the burners of a considerable number of boilers.
4. No wear and tear of grate bars.
5. No dust, no ashes, and no clinker.
6. When once arrangements have been made, the storage of oil fuel is simpler than the storage of coal, and oil does not deteriorate.
7. The control of the steam production is easier, more effective and more rapid than with solid fuels.
8. Instantaneous ignition, and extinction of the fire.
9. No smoke.

The three main systems for burning oil fuel are:—

1. That in which STEAM is used as a spraying or atomizing agent.
2. That in which AIR is used for this purpose.
3. That in which the oil is atomized mechanically by PRESSURE.

We would be glad to go into details with a prospective purchaser.

BABCOCK & WILCOX, LIMITED

HEAD OFFICE FOR CANADA - COLLEGE ST. (ST. HENRY), MONTREAL

TORONTO OFFICE: BANK OF HAMILTON BUILDING

MR. BLACKBURN

(Continued from page 38)

cates are good for life, while in most other provinces engineers' certificates must be renewed each year.

"These difficulties amongst others could no doubt be overcome if the question was fully considered at an interprovincial conference of the examining bodies of each province, and engineers' certificates might thus be placed on a uniform basis, but special legislation would be required in nearly every province. Any arrangements made at such conference would have to be confirmed by the respective provincial legislatures, and on account of the many conflicting interests that would be involved it might be very difficult to get uniform legislation passed.

"It has been the practice of the Steam Boilers Branch for a number of years to grant Saskatchewan certificates to holders of engineers' certificates granted by other provinces, who produce satisfactory testimonials from former employers, etc., without further examination. Where the standard of examination is equivalent to our own, a certificate of the same grade is usually granted, but where the standard of examination is lower, a certificate of a grade only which is considered equivalent to the standard of examination passed by the holder is granted This meets the case of engineers coming into this province from other provinces fairly well, but as similar liberal treatment is not invariably accorded to holders of Saskatchewan certificates when applying for certificates in other provinces, the present arrangement cannot be considered as entirely satisfactory."

CELITE OPENS CANADIAN OFFICE

Celite Products, Limited, has recently been established in Canada, with offices in the New Birks Building, Montreal, to market the products of the Celite Products Company, who have sales offices in the principal cities in the United States.

The products of this company are sil-o-cel insulating brick, sil-o-cel powder, filter-cel for better filtration.

Sil-o-cel insulating brick for the prevention of heat loss through radiation are largely used for the insulation of boiler settings, brick kilns and all other types of heated equipment. The loss of heat through radiation is practically eliminated, which means a direct saving in fuel. Other advantages claimed for this product are: Increased capacity of the equipment; more uniform temperatures, and better working conditions.

Montreal office is in charge of Lawrence Russel, and complete stocks of various sil-o-cel products are maintained there. This company recently furnished all the insulating brick for the boiler equipment at the new plant of the St. Lawrence Paper Mills, Three Rivers, Que.

COMBUSTION ENGINEERING

Engineers and purchasers of power plant equipment in Canada will be interested to learn of the incorporation, under a Dominion Charter, of the Combustion Engineering Corporation, Limited, with an authorized capital of $250,000. The head offices of the Company are at Toronto and branches are being established at Montreal, Winnipeg, and Vancouver. A. J. T. Taylor, A.S.M.E., A.I.E.E., a well known Canadian mechanical engineer is president and managing director. Wilfred R. Wood, managing director of the Underfeed Stoker Company, London, Eng., is vice-president. George Usher of the Societe Anonyme des Foyers Automatiques, Paris, is a director, and John Anderson, is secretary-treasurer.

The new Corporation has acquired the sole manufacturing and sales rights in Canada for the complete line of power plant equipment owned by the Combustion Engineering Corporation, New York; The Green Engineering Co., Chicago; The Coxe Travelling Grate Company, Port Carbon, Pa.; The Coshochton Ironworks, Monongahela, Pa.; Underfeed Stoker Co. Ltd., London, Eng.; International Pulverized Fuel Corporation, New York and Lopulco Systems Inc., New York.

These various companies represent collectively one of the most complete line of steam power plant equipment ever brought together. It includes all types of mechanical stokers, pulverized fuel burning systems, ash conveyors, ash hoppers and air heaters.

In addition to these lines, which cover the whole range of fuel burning equipment, the new company will sell in Canada, economisers, soot blowers, induced and forced draft fans, Custodis radial brick chimneys and recording instruments, in short everything in the boiler house except the boilers. They will manufacture as much of this equipment as possible in Canada.

It is the Corporation's intention to co-operate with all consulting engineers and will place freely at their disposal the services of their engineers. By an arrangement with the International Combustion Engineering Corporation they will have the benefit of the advice of such internationally known engineers as Henry Kreisinger, research engineer, formerly of United States Bureau of Mines, John Van Brunt, chief engineer, Combustion Engineering Corporation, John E. Bell, consulting engineer, New York; T. Marsh, chief engineer, Green Engineering Co., Samuel McEwen, chief engineer, Underfeed Stoker Co., London; I. Beuzit, chief engineer, Societe Anonyme des Foyers Automatiques.

The Combustion Engineering Co. Ltd., is establishing a research dept., to give special attention to some of the fuel problems of Canada particularly in regard to the coals of Western Canada. John T. Farmer, M.E.I.C., A.S.M.E., Montreal, is chief engineer for the Corporation.

The Corporation already has important work in hand for the Imperial Oil Company and The Ford Motor Co., and many installations of its equipment are in successful operation throughout Canada. The Corporation is in a position to select from the best British, French and American practices, those pieces of apparatus that best fit the particular problem and then combine them to suit the special conditions.

Mr. Taylor, executive head of the Corporation is thoroughly experienced in Canadian engineering practice and has done notable power plant work covering a wide range in the industrial field. He is a member of many of the leading engineering societies, among them the A.S.M.E., A.I.E.E., A.I.M.M., C.I.M.M., is a Canadian by birth and will be ably supported by J. T. Farmer, of Montreal, whose reputation as a mechanical and hydraulic engineer is thoroughly established. Mr. Farmer is chairman of the Montreal section of the A.S.M.E. this year.

Winifred P. Wood, London, is an authority on combustion problems, while G. C. Usher, will be remembered in this country as the former general manager of the Green Fuel Economizer Co., which position he left two years ago to return to England. He is now in France in charge of important developments in combustion engineering equipment now being undertaken by the Societe Anonyme des Foyers Automatiques.

TORONTO C. A. S. E.

A meeting of No. 1, Toronto C.A.S.E was held in Cumberland Hall on th 6th inst., when a very interesting pape was read by R. McLaren, upon "Th desirable auxiliaries in a power-plant.' This was greatly appreciated by al those present, who after an interestin discussion showed their appreciation i the usual way. There was only on officer absent from his accustome chair, which vacancy was temporaril filled by the Engineer's friend, Howar Fletcher who explained in his bes style, for the benefit of new member the meaning of C.A.S.E.

On the evening of Thursday, the 15t the Joint Executive Committee of th No. 1, Toronto C.A.S.E., and the Ex hibitors' Association met in the Centr Technical school to decide and mak final arrangements for the coming co vention, which is to be held on Jun 25-28.

Fredericton, N. B.—There is a poss bility of the Grand Falls on the St. Joh River being developed by the Provinci Government. The Grand Falls powe rights have been held for some years b the Grand Falls Company, that is co trolled by International Paper Compan interests. Their rights expire ne April.

Pulverized Coal

THE AERO UNIT SYSTEM

Reduces the equipment and the operating cost to a minimum. The coal is received undried and exhausted directly into the furnace. Greater efficiency, mechanical simplicity and ease of control feature the Aero installations.

ROLE OF THE ENGINEER

Engineering was represented at the Boston gathering of the American Association for the Advancement of Science last week in two of the many sections—Section K (social and economic sciences), of which Dr. Henry S. Graves of the Yale Forestry School is chairman, and Section M (engineering), of which the chairman is F. M. Feiker, vice-president McGraw-Hill Company, Inc. At a joint session of the two sections John T. Black, State Health Commissioner of Connecticut, spoke on "Conservatism and Industrial Waste," and William S. Murray, New York, on "Conservation of Power." O. C. Merrill, executive secretary of the Federal Power Commission, and Gen. Harry Taylor, Corps of Engineers, U. S. A., were unable to present their papers because of badly delayed train schedules.

"The Place of the Engineer in Civilization" was the keynote of the meeting of Section M. Dr. Ira N. Hollis, president of Worcester Polytechnic Institute, led the discussion, instancing the factors of transportation and communication as vitally touching the activities of men in every walk of life and dwelling on the need for the engineer to make an analytical study of the facts governing the solution of present-day problems. A similar point of view was expressed by Harrington Emerson, who alluded, as did Dr. Hollis, to the engineer's control of the instruments of production. Dr. J. B. Tyrrell told of the growth of the mining industry in Canada. The paper of C. F. Scott, professor of electrical engineering at Yale, was read in his absence by Dr. D. C. Jackson. It dealt with new phases of engineering education and pointed out that the large part played by engineering in modern life made it essential that the training of engineers be approached with a new viewpoint of the engineer's place in the community.

NEW PUBLICATION

Machinery Foundations and Erection, by Terrell Croft, 5½ in x 8 in., cloth bound, 690 pages, first edition published by the McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York.

This book will fill a long felt need with engineers who have the excavating, laying-out and setting of concrete foundations for the installation of all forms of prime movers and machinery. He will have no difficulty whatever from the worked out examples and liberal illustrations to successfully lay out his foundations in the most practical, up-to-date and approved manner. The author has been successful in simplifying all mathematical formula, and has treated with his subject in such a manner, that a very ordinary knowledge of simple arithmetic is all that is necessary to install a safe foundation for any machinery, at the same time keeping within the bounds and confines of good mathematical practice. The subject is treated with in a very exhaustive manner and the book is indispensible to the practical engineer.

New harbor facilities for Vancouver, B. C.—A resolution proposing the loan of five million dollars has been well received in Federal parliament. This bill has been given its first reading. Hon. Ernest Lapointe, Minister of Marine, states that Vancouver is in line for a huge Oriental trade. These new facilities are necessary to compete with Seattle. With these improved conditions a Saskatchewan farmer could ship grain to England via Vancouver for 8 cents a bushel cheaper than via eastern ports. The rate to Liverpool via Vancouver—39-2/5 cents per bushel. Via eastern route—47-3/5 cents per bushel.

Toronto Engineers' Club have elected the following officers for the ensuing year: W. R. McRae, president; E. G. Hewson, first vice-president; A. B. Cooper, second vice-president; George G. Powell, third vice-president; R. B. Wolsey, secretary-treasurer; J. C. Armer, chairman of House Committee; J. B. Carswell, chairman of Finance Committee; Frank R. Ewart, chairman of Admission Committtee; George R. Mickle, chairman of Library Committee. The other members of the Board of Directors are W. G. Gordon, T. D. LeMay, Balmer Neilly, A. V. Thimble, John van Nostrand, A. F. Wells and E. W. Wright.

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we willtell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

FOR SALE

TAYLOR SAFES FOR SALE—RARE OPPORTUNITY to secure a safe at small cost. They are in splendid condition. **Inside** dimensions and prices are as follows: 15" deep, 2 ft. 6" wide, 3 ft. 11½" high, fitted with built-in compartment. Price $250.00. 18" deep, 2 ft. 8" wide, 4 ft. 5" high, fitted with steel compartment. Price $200.00. Apply Box 10, POWER HOUSE.

FOR SALE

BOILERS FOR SALE CHEAP—TWO 100 horsepower, 110 pound steam. Apply Box 102 Power House.

BURNHAM STEAM PRESSURE PUMP, 10 IN. x 1⅛-inch. x 12 in., nearly new, with Fisher governor attached. W. Ahearn, 538 McLaren St., Ottawa. When answering this advertisement please mention this paper. P.F.H.

FOR SALE ONE 10 H.P. STEAM BOILER with base and 20 ft. smokestack; new flues and in A1 condition; also 1 steam turbine bottle washer and sterilizer; both in excellent working order Apply Box 103 Power House.

INDUCTION MOTOR — 220 VOLTS — 1800 r.p.m. 15 h.p.; single phase; can be bought cheap; write for particulars. Box 104, Power House.

I. H.C. 12 H.P. GAS ENGINE FOR SALE—ALL in good running shape, with 33-inch clutch pulley; will be sold reasonable on easy terms. Apply W. Harrison & Son, R. R. No. 5, Guelph. When answering this advertisement, please mention this paper. P.F.H.

SAWMILL MACHINERY—MODERN DESIGN—most satisfactory to operate. Apply Box 105, Power House.

SAWMILLS—PORTABLE — DOUBLE EDGES; also all kinds sawmill machinery. Apply Box 106, Power House.

WELDING

ELECTRIC AND ACETYLENE WELDING of broken castings and machine parts, boilers, tanks, and marine repairs. Carter Welding Co., Ltd., 165 Adelaide West, Toronto. Adelaide 2841.

BELTING BARGAIN

ABSOLUTE BELTING BARGAINS—BELTING every description; rubber hose, thresher supplies, tank pumps, pump leather feeds, canvas, McGill auto powers, special reduced prices; for quality and price, you can't beat us. N. Smith, 134 Adelaide west, corner of York, Toronto. When answering this advertisement, please mention this paper. P.F.H.

BELTING OF ALL KINDS—NEW OR USED pulleys, saws, cable, hose, etc., shipped subject to approval at lowest prices in Canada. York Belting Co., 115 York St., Toronto.

REPAIRS

A. D. FISHER MANUFACTURING CO., 77 Front St. East, are prepared to build special machinery, dies, tools and all kinds of repairs; prompt service.

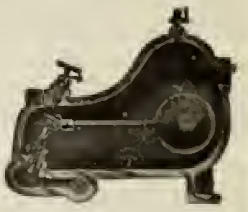
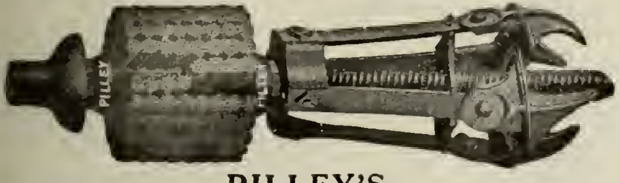
THE GARTH COMPANY
Craig Street—MONTREAL, CAN.

WATSON & McDANIEL CO.
No.146 N. 7th St., PHILADELPHIA, Pa.



The Simplest and best cleaner on the market is



PILLEY'S

Combination Flue Brush and Scraper.
Guaranteed not to break or the wires to pull out or lay over. A simple turn of the hand adjusts it to the tube, and the brush removes what the scraper loosens.
For sale by leading Canadian jobbers.
Manufactured by
PILLEY PACKING AND FLUE BRUSH MFG. CO.
623 South Third Street - - - St. Louis, Mo.
Eastern Office: 71 Fulton St., New York.

"Pop Off" Steam
Carries Ashes Away

"Into the hole and away they go" describes ash removal with a Green Steam Jet System. At the Kewanee Boiler Co., they use "Pop off" waste steam to do the work.

A Reasonable Saving of 5 to 10%

Should You Expect More?

WE GUARANTEE that with the use of CYCLONE SHAKING AND DUMPING GRATE any grade of hard or soft coal, or screenings of same, can be burned with excellent results both as regards Economy and Capacity; that the total annual expense to the user for coal, interest, depreciation, repairs, damage to boiler, liability of shut-down, etc., will be much less than would be the case with any other type of Grate or Stoker on the market.

Increase furnace life two to four times with PLIBRICO

JOINTLESS

FURNACE LINING

Send for this book; fifty pages of furnace facts free—

Both photographs above are of the same furnace taken after the same amount of service. At the left the crumbled side wall is an unanswerable argument against laid up fire brick; at the right the staunch, jointless walls are a sermon for Plibrico Furnace Lining.

Plibrico is a plastic furnace lining that can be applied by anyone who can use a mallet; when baked it forms a rock-like, gas-tight jointless lining that resists temperatures to 3100 deg. F. and that outlasts ordinary fire brick two to four times.

Plibrico is stocked in principal cities and is delivered only in steel containers of distinctive appearance as shown below.

DISTRIBUTORS: Beveridge Supply Co., Ltd., Montreal; Shell Bar Boico Supply Co., Ltd., Toronto; Evans, Coleman & Evans, Vancouver, B.C.; Winnipeg Supply and Fuel Co., Winnipeg; Gorman's Ltd. Calgary, Alta.

A COMPLETE SERVICE IN

"John Crane"

FLEXIBLE METALLIC PACKING

"Made in Canada"

PACKING THAT LASTS

John Crane packing of spirally wound babbitt foil impregnated with graphite wear as only a non-corrosive, non-abrasive metal can. Its simplicity is its strength—flexible, compressible, easily applied using the piston rings principle of the fluid seal. John Crane packings give length and quality of service previously unequalled in packing. Send for our text book "Metallic Packings."

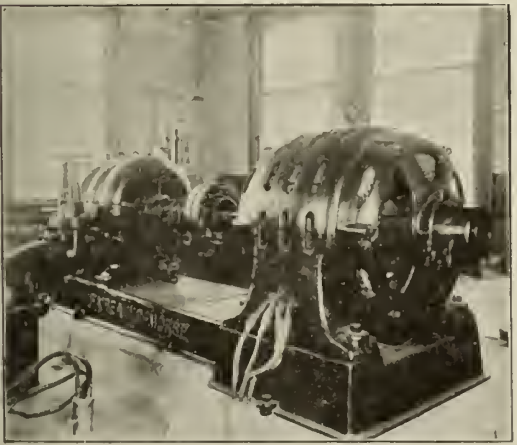
The Heart of the Pumping System

The FAIRBANKS-MORSE Centrifugal Pump



Particularly adapted to Municipal Water Supply, High Pressure Irrigation, Marine Service, Hydraulic Elevator Service, water supply for mills, office buildings and apartment houses, etc.

These renowned pumps have a long record of continuous satisfactory service. They are of extra rugged construction, and all bearings are renewable bronze, while they may be opened quickly for inspection without disturbing pipe connections.

We supply practically every type of pump, be it Air, Boiler Feed, Centrifugal, Fire, Marine, Gasoline, Heavy Oil, Irrigation, Rotary, Hydraulic or Typhoon, etc., and our engineers will gladly recommend the proper type for your conditions without charge or obligation. Write our nearest office for Pump data.

When Writing Advertisers Please Mention
POWER HOUSE — *That is Your Introduction*

Value of Business Newspapers

Recognized by Daily Press

FORTY publishers in Chicago recently formed an association to promote the morning newspapers' interests in competition with the evening newspapers as an advertising medium. They have announced their intention of employing the business newspapers for publicity purposes in furthering their aim.

This recognition of the place and power of the business newspaper coming as it does from daily newspaper men who know better than most people the necessity of discrimination by advertisers in selecting their publicity channels, is a striking tribute to the value of the business newspaper as an advertising medium.

These publishers realize that the business papers reach the most important men in every industry, the men whose opinions count, and who have most influence in the business world. And not only do the business papers reach these men but they are also read by them. Many business men are not great readers, but the papers which they must read—which they cannot afford not to read—are those which deal with their own business and give the news connected with it.

The following business publications are all leaders in their own field and by their means you can send your sales message to the leading men in the industries they cover. All the papers are members of the Audit Bureau of Circulations, which is a hall-mark or guarantee of quality-circulation. Information regarding circulation, advertising rates and fields covered, will be furnished on application.

The YOUNG

Centrifugal Vacuum and Boiler Feed Outfit

Designed for Vacuum Heating Systems and for All Conditions Where a Wet or Dry Vacuum is Desired—Highly Efficient

This simple, inexpensive and noiseless outfit is used with perfectly satisfactory results with Dry Kilns, Paper Driers, Feed Driers, Print Mills, Cooking Apparatus, Vacuum Pans, etc., for the purpose of effecting a saving by returning the condensate for boiler feed.

MONCRIEFF'S "UNIFIC" WATER GAUGE GLASSES

Moncrieff's "Unific" is not a cheap glass. But because it outlasts many ordinary glasses the "Unific" is economical. British Made.

MONCRIEFFS "UNIFIC"

JOHN MONCRIEFF LIMITED
PERTH, SCOTLAND

The "Unific" does not readily corrode. It resists extreme changes of temperature and withstands the highest working steam pressure.

Constant Delivery Pressure

Mueller Reducing and Regulating Valve A-5030 is specially constructed for use on exacting installations. It will reduce as desired and deliver at a uniform pressure regardless of variations in initial pressure. It is a single seat, auxiliary operated valve for water, gas and air and is made in sizes from 1¼" to 12".

Mueller makes valves for all purposes. Write and tell us your problems and we will give you the solution to them.

Power House, Point du Bois - View from Tail Race

Harnessing the Waters of the Winnipeg River

CANADA CEMENT CONCRETE FOR PERMANENCE

THE development of water power within economic transportation distance of Winnipeg, has reached a point where 70,000 horse power is available, and there is sufficient additional reserve power to develop 500,000 h.p. when required.

At the power house site, the Winnipeg River falls over a series of rapids with a natural fall of 33 to 28 feet within a ¼ mile. This fall is increased to a total head of 43 to 48 feet, by a concrete dam; giving a pondage area of 7 sq. miles.

The power house, completed in 1920-21 is of concrete and steel. The power house foundations, consisting, besides the series of draft tubes, of a series of flat tail race arches upon supporting walls tapered in plan, were built in pairs of arches; the two adjacent spans, built as a unit with a mid-wall, are resting upon asphalt painted skewbacks formed upon alternate tail race walls. The contraction joints are thus 56 ft. apart. By this means the use of reinforcing steel in these arches was avoided.

In the other elevation of the building the foundations were separated into three portions—the arrester bays, the transformer and generator room and the turbine and rack rooms. This was done by the use of two vertical expansion joints, running the entire length of the building. Above the tail race arches, parting planes, asphalted and keyed with wooden strips, were provided in the main walls, with considerable success in the effort to avoid unsightly cracks.

This great plan of hydro-electric development at Point du Bois has given Winnipeg power at the lowest rate on the continent, less than a half cent per K W H.

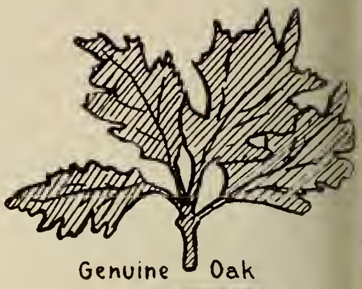
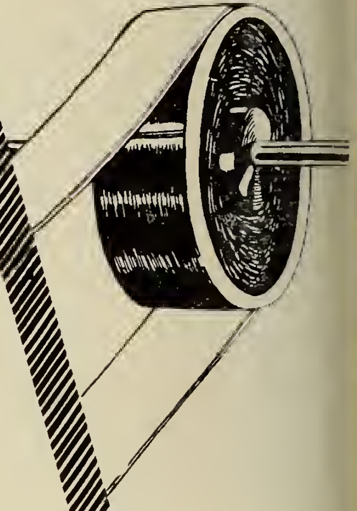
D.K.McLaren's

Genuine British Oak Tanned

Leather Belting





Belting that's Built For Better Service

The **back portions** only of flawless hides, chosen by experts, are just the beginning of D. K. McLaren's Leather Belting. Tough as these portions are, they are made tougher yet by being subjected to

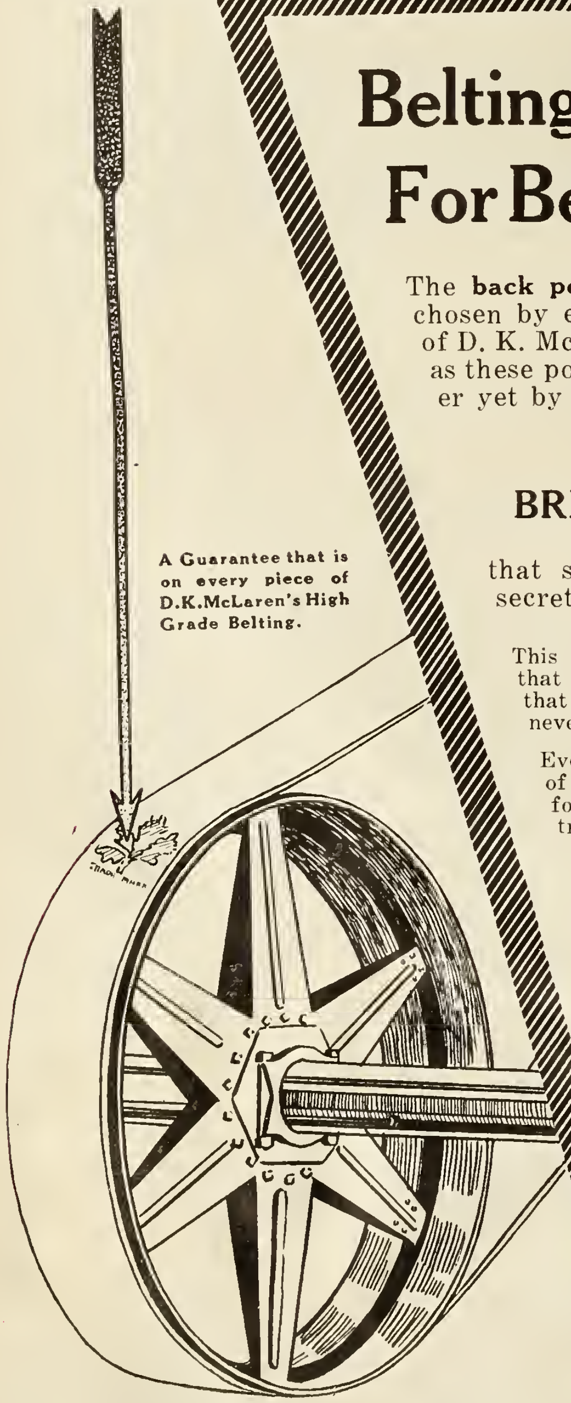
GENUINE BRITISH OAK TANNING

that slow and one-time closely guarded secret process of English Tanners.

This not only adds to the toughness but imparts that wonderful flexibility and "stretchless quality" that gives to D. K. McLaren's Belting "A Grip that never slips."

Even under adverse conditions the built-in quality of D. K. McLaren's Belting marks it as Belting Built for Better Service—a service reflected in minimum transportation costs.

The Oak Leaf stamped upon every length is your guarantee of this "trouble-free" service. Be sure to look for it.



A Guarantee that is on every piece of D.K.McLaren's High Grade Belting.

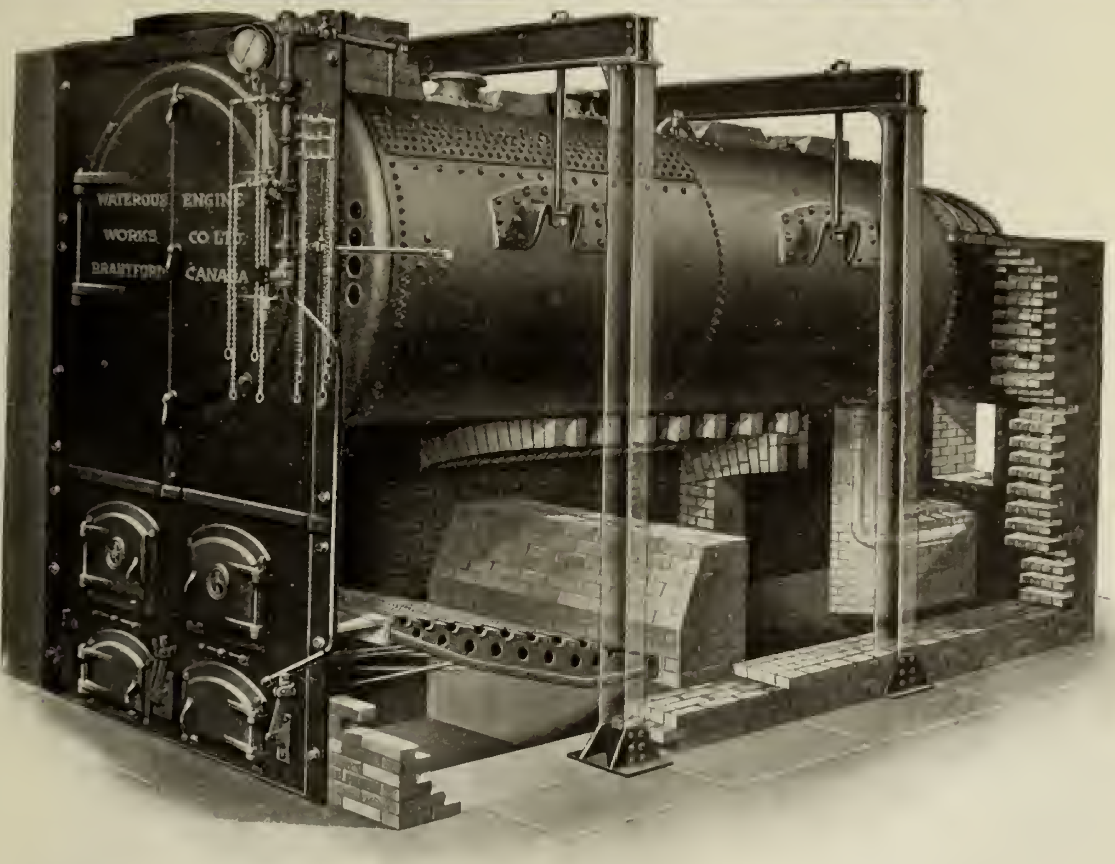
Files Stokers

Hand Operated



"Are Giving Absolute Satisfaction"—

S. KANN SONS COMPANY, Washington, D.C.

"In answer to your communication of Aug. 1st in reference to our **Files Stokers,** will state that they are giving **absolute satisfaction.** We have them installed under two 250 H. P. Heine Boilers.

"While we have not made a test of the actual saving in coal, would judge from 10 to 15% as our load increased 25%. We were able to carry steam without difficulty, which we could not do when our boilers were equipped with the down-draft furnaces.

"Our smoke laws in this city are very strict and with one or two exceptions we have always been able to comply with same. With careful firing there should be very little smoke. Our expense for upkeep has been very reasonable.

"Hoping this information is what you desire, we remain,

"Yours very truly,

"THE S. KANN SONS COMPANY."

LUNKENHEIMER
Safety Non-Return Valves

The rupture of one boiler connected with others in battery may cause considerable damage, but if MEANS are provided whereby pressure from the other boilers is instantly prevented from escaping through the ruptured one, not only is further damage avoided but the operation of the plant, through the medium of the live boilers, may be continued with perfect safety to the operatives.

A Lunkenheimer Safety Non-Return Valve provides the MEANS.

Furnished in Iron Body, Bronze Mounted Pattern for pressures up to 250 pounds, 450° F. total temperature and in Steel, Monel Mounted, for 350 pounds pressure, 800° F. total temperature. For detailed information, write for catalog No. 58-DC.

Diamond Soot Blowers

The Best Paying Investment in the Boiler Room

BECAUSE:
They save 4 to 8 per cent fuel—one carload out of every twelve to twenty-five which enter your yard.

They save steam and labor, and labor turnover. The dollars and cents value of these savings alone in one year is more than the initial cost of the soot blowers.

They completely solve the soot blower problem. Satisfactory operation under the severest furnace conditions is at all times assured. Soot blower maintenance is reduced to a minimum.

Dollar for dollar invested the net savings effected by their use amounts to more money each year than can be earned by any other single piece of boiler or engine room equipment.

REMEMBER there is only one "Valv-in-Head" soot blower—the DIAMOND—and that the blower elements are protected by a special process developed by the General Electric research laboratories—CALORIZING.

A Booklet which belongs in the library of every executive who is concerned with the cost of power production is yours for the asking. SEND FOR YOUR COPY OF BULLETIN 287

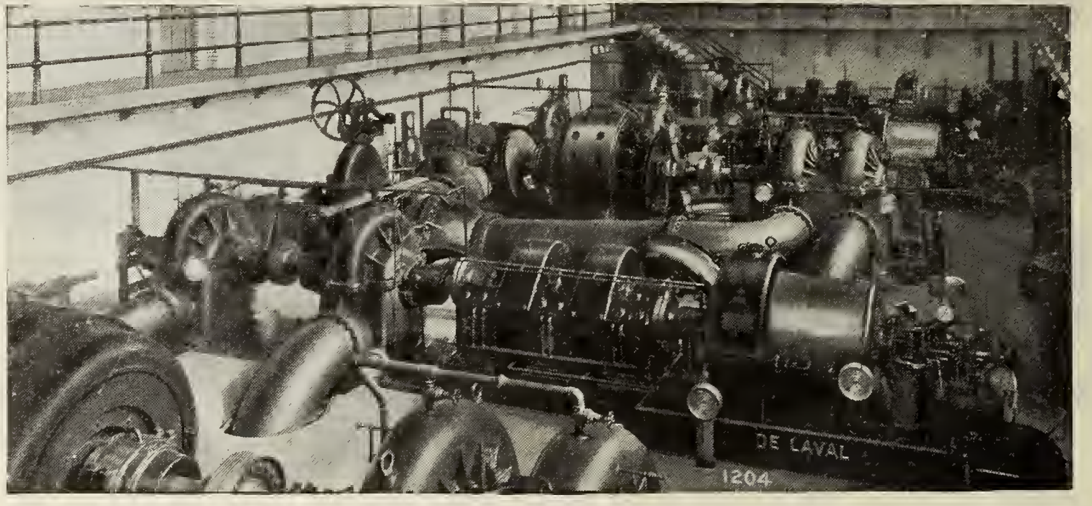
Automatic Valved Soot Blowers

Diamond "VALV-IN-HEAD"



Records Made at Toronto by De Laval Pumps

THE John Street Pumping Station at Toronto contains three De Laval Geared Turbine Driven Centrifugal Pumps having a capacity of 24,000,000 Imperial gal. each against 250 ft. head. The first unit installed was designed for a capacity of 15,000,000 Imperial gal. per day but provision was made for changing the capacity later to 24,000,000 Imperial gal. per day. This first unit, when tested by Prof. R. W. Angus in the year 1914, set the high record of 130,449,000 ft. lb. per 1,000 lbs. of steam when pumping at a capacity of 15,000,000 gal. per day, which duty had never before been reached by a steam turbine driven pump. One of the 24,000,000 gal. pumping units when tested by Prof. Angus in 1917, however, put the record up to 153,920,000 ft. lb. per 1,000 lb. of steam, which has only lately been surpassed by De Laval units of somewhat larger capacity and power. Efficiencies of over 87% were obtained at the official tests made by Prof. Angus of four 20,000,000 Imperial gal. per day motor driven De Laval pumps for 250 ft. head, recently installed at Toronto. The De Laval Steam or Electric Driven Centrifugal Pump is the most economical means for handling water. Ask for book W-100 on "Ten Years' Progress in Water Works Pumps."

DIRECT-CONNECTED SYNCHRONOUS
MOTOR DRIVEN AIR COMPRESSORS

Where requirements call for a compressor with a capacity of over 700 ft. per minute, and if you want electric drive, the Class "PRE" is the logical selection. The number of these machines installed in all parts of the world and the variety of industries served is proof of the fundamental engineering principles of their design and construction.

Direct-connected synchronous motor drive is efficient because the driving power is transmitted directly to the compressor shaft, avoiding belt losses and breakages. Standard unity power factor synchronous motors will improve the power factor of your electrical system—if desired a leading power factor motor can be installed to bring your line still closer to unity power factor. Also, the complete machine is compact and requires a simple foundation.

A distinctive feature of Class "PRE" Compressors is their **patented** 5-Step Clearance Control which causes the compressor to operate automatically at full, ¾, ½, ¼ or no load, depending upon the amount of air being used.

An enclosed dirt-proof flood lubrication system automatically furnishes copious lubrication to all running parts; force-feed lubricators oil the air cylinders.

Class "PRE" Compressors are furnished complete with standard self-starting synchronous motor, exciter and starting panel, or with direct current motor and panel. When requesting details, specify your electrical conditions.

Garlock Packings

Have you ever considered the loss in engine efficiency due to excessive friction on piston and valve rods caused by the use of inferior and poorly lubricated packing?

A horse power easily can be absorbed at the stuffing box and, when, considered in dollars and cents at the coal pile, the loss would pay for a high class packing many times over.

Garlock packings are designed to meet every condition of service.

Write for Catalog.

Jenkins Rapid Action Valve

Can be opened and closed instantly without water hammer

The carefully worked out design and enacting construction of this valve make it absolutely dependable in services where a quick opening waterhammerless valve is needed.

A slight pull of the lever is sufficient to provide full opening and it stays open without the aid of set screws, locking devices or other appliances. Closes instantly with slight pull of lever. Stops water waste. Saves time.

Illustrated literature fully describing this Jenkins Rapid Action Valve will be mailed you on request. Write for it to-day.

Men! Protect Yourselves With This Time Punch

Many a faithful employee, conscientiously performing his duties, in connection with heat-treating processes, has had to stand the blame for heavy spoilage in the past—simply because he couldn't prove that he was on the job.

In every manufacturing process calling for temperature control you can now protect yourself against unjust reprimand by means of the TIME PUNCH attachment of the Columbia Recording Thermometer.

The Day-and-Night Chart furnishes a true record of temperature variations, but the Time Punch, operating exactly like a time clock, registers the very minute of your visit, showing beyond question that you watched the chart at stated intervals. Your employer doesn't have to take your word for it—the little punch hole in the margin of the disc, made at the instant you press the button, backs you up in your assertion that you kept your eyes on the temperature. It proves that you were faithful in the discharge of your duties.

As a matter of self-protection urge your Superintendent to install Columbia Recording Thermometers with Time Punch attachment. They cost no more than ordinary recording thermometers without this valuable feature.

The Time Punch attachment is also supplied on Columbia Recording Gauges and Tachometers.

Write to-day for catalog H-33.

The government-proved bearing metal

Magnolia Anti-friction Metal has been proven by United States and foreign government tests to have the lowest frictional coefficient of any known bearing metal. This fact alone clearly establishes its superiority to ordinary babbitts.

And there are additional reasons for the wide popularity of Magnolia Metal. It melts and pours well, is easily peened and scraped in, is always uniform in composition, adapts itself quickly to shaft inequalities and gives long and dependably good service.

A single trial will quickly prove the advantages of Magnolia Metal. If your dealer can't supply you, write direct to our nearest office. 20

Special Foxboro
DRAFT RECORDING ATTACHMENT

A record of draft over the fire, on the same chart as the CO2 record, has the advantage of bringing two related records together for convenient comparison. The improved Foxboro diaphragm tube movement which has proved so satisfactory for measuring draft is combined with the standard CO2 Recorder to make an exceedingly reliable combination recorder.

Our friends who have installed Foxboro-Heath CO2 Recorders in their plants tell us that they have an exact knowledge of combustion efficiency at their finger tips, and that they never have to worry about the reliability of their source of information.

The Foxboro-Heath CO2 Recorder is a practical, common sense instrument for accurately recording CO2 content in flue gases. It is of all metal construction; no glass parts to break or rubber tubes to leak. There are only three moving parts.

Five minutes attention a day and twenty-five minutes at the end of each month keep the instrument in perfect working order.

In accuracy and dependability the Foxboro-Heath CO2 Recorder meets its full responsibility in upholding the Foxboro reputation as "The Compass of Industry."

Let us show you how the Foxboro-Heath CO2 Recorder can lighten your combustion burdens. Write to Dept. C.F.

Asphalt mastic finished Nonpareil Corkboard on the walls and ceiling of the ice storage house of the Illinois-Public Service Corp., Abilene Power Plant, Abilene, Texas.

Asphalt Mastic Finish Here

AIR-PROOF, moisture-proof, frost-proof—asphalt mastic finish on Nonpareil Corkboard insures the maximum efficiency of your insulation. It prevents moisture penetration and the consequent formation of frost which sometimes destroys plaster finishes in ice storages, hardening rooms, coil bunkers, etc., when the temperature is low and humidity high.

Asphalt mastic finish is a special grade of odorless, refined asphalt, $\frac{1}{8}$-inch thick, ironed on one side of the sheets of Nonpareil Corkboard at the factory. The ironing keys the finish into the corkboard and assures uniform application without voids or air holes. Asphalt mastic will not run or peel at ordinary temperatures, nor will it crack when cold. The joints are sealed with a mastic filler. No plaster or other finish is required.

Asphalt mastic on Nonpareil Corkboard stands up under the most severe cold storage conditions of moisture and temperature and protects your insulation permanently.

Write for a sample of asphalt mastic finish Nonpareil Corkboard. It will be sent free on request, and further information and estimates will be gladly furnished without any obligation on your part.

PLASTIC FIRE BRICK

Makes practicable, solid, one-piece furnace lining, including front and back arches, side walls and baffles. It costs but little to install in any make or type of boiler. It saves fuel, annoying shut-downs, costly repairs, and increases the amount of power from the fuel used.

Complete details of the many uses, methods of installing, how to order, measurement blanks, etc., are contained in a booklet of information which we will gladly send you. Tell us the individual to whom it should be addressed.

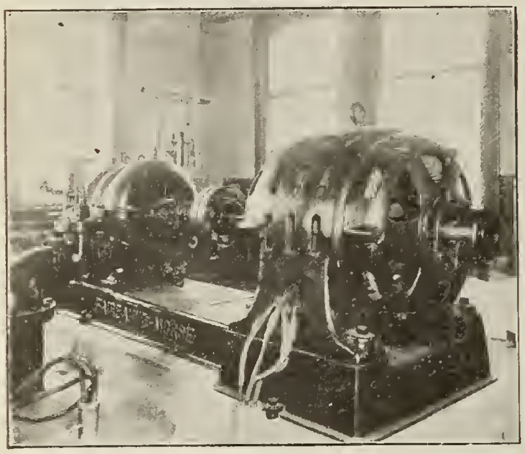
The Heart of the Pumping System

The FAIRBANKS-MORSE Centrifugal Pump



Particularly adapted to Municipal Water Supply, High Pressure Irrigation, Marine Service, Hydraulic Elevator Service, water supply for mills, office buildings and apartment houses, etc.

These renowned pumps have a long record of continuous satisfactory service. They are of extra rugged construction, and all bearings are renewable bronze, while they may be opened quickly for inspection without disturbing pipe connections.

We supply practically every type of pump, be it Air, Boiler Feed, Centrifugal, Fire, Marine, Gasoline, Heavy Oil, Irrigation, Rotary, Hydraulic or Typhoon, etc., and our engineers will gladly recommend the proper type for your conditions without charge or obligation. Write our nearest office for Pump data.

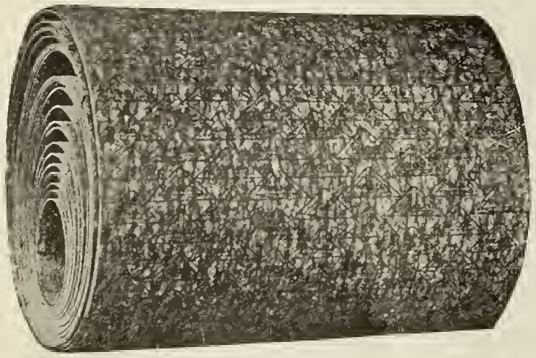
Durabla Gaskets Make Tight Joints

Extreme tests prove that Durabla Gaskets can withstand all Temperatures and Pressures without showing signs of Distress.



Wherever a permanent Gasket is required use Durabla. Durabla Compressed Asbestos Fibre Gasket Material makes tight joints on Steam, Water, Air, Oil, Ammonia and Acids. It will not burn out, blow out or pulp at the joints. Durabla is made in convenient size sheets that can be rolled and unrolled. Stamped with the Durabla trade-mark which guarantees strength, goodness and quality.

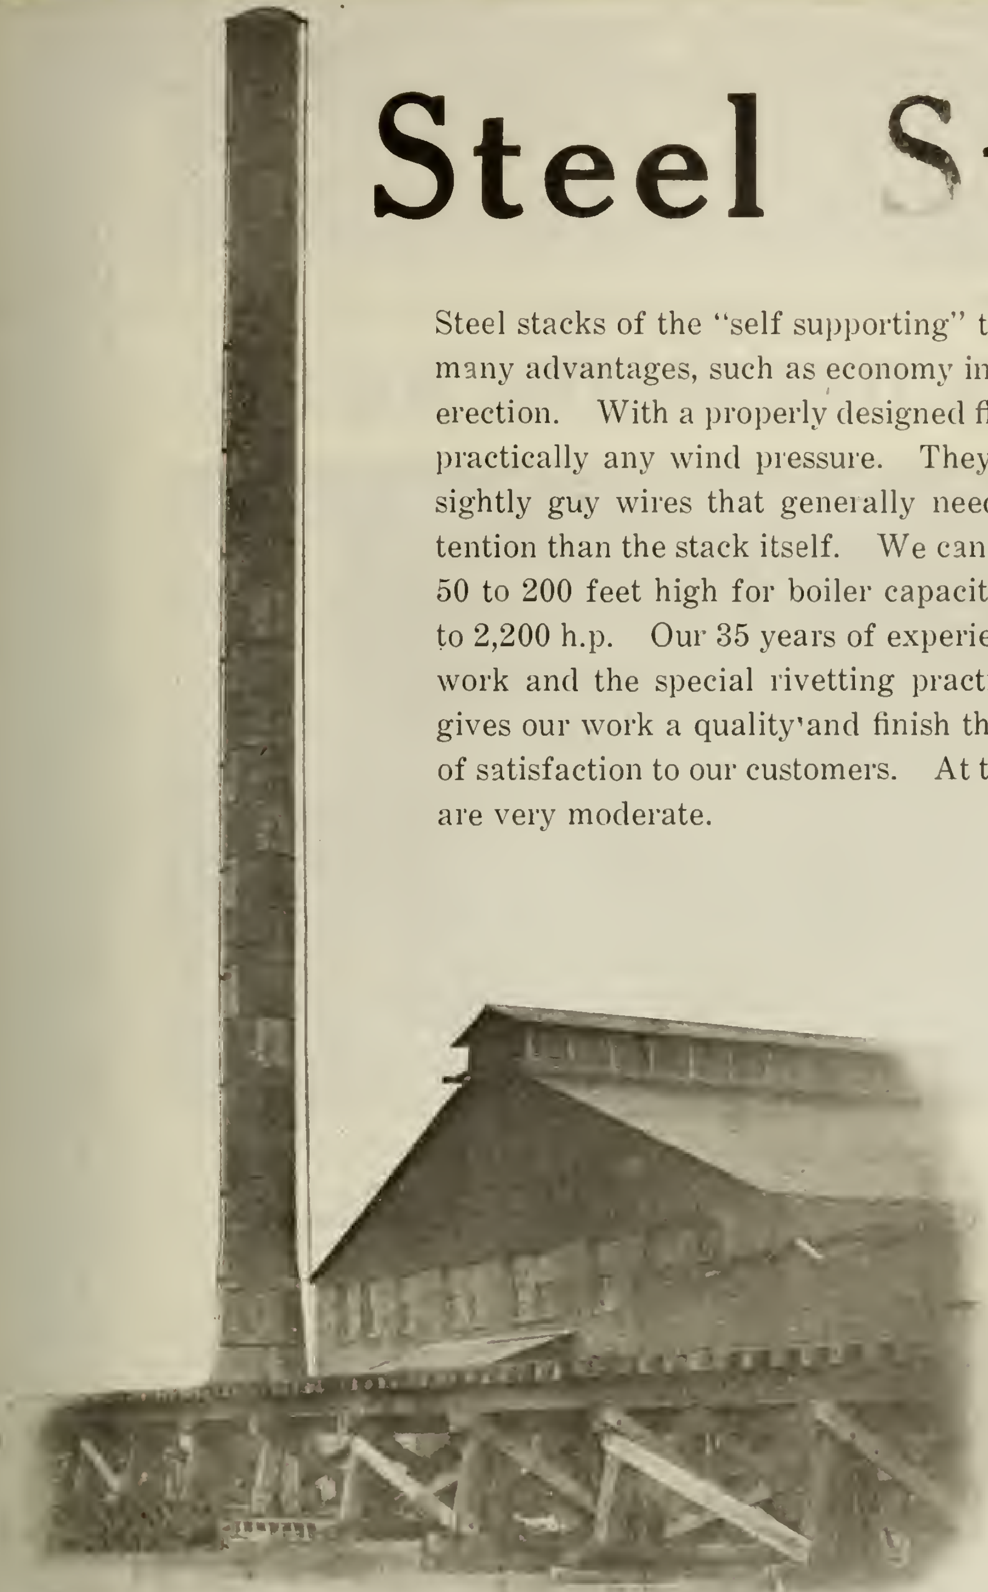
Steel Stacks

Steel stacks of the "self supporting" type as illustrated, offer many advantages, such as economy in cost and time saved in erection. With a properly designed flare base they can stand practically any wind pressure. They do away with the unsightly guy wires that generally need more repairs and attention than the stack itself. We can build these stacks from 50 to 200 feet high for boiler capacity running from 20 h.p. to 2,200 h.p. Our 35 years of experience in high grade plate work and the special rivetting practice we have developed gives our work a quality and finish that is a continual source of satisfaction to our customers. At the same time our prices are very moderate.



A self supporting steel stack, 140 feet high, 6 feet, 6 inches diameter, erected by us for Pilkington Bros., Limited, Plate Glass Works, Thorold, Ont.

With Temperature at 24° below Zero Ottawa Collegiate Boilers are Highly Satisfactory

The following letter from the Architect speaks for itself.

Office of J. ALBERT EWART, B.A Sc., Architect,
Jackson Building, Ottawa, February 6th, 1923.

THE GOLDIE & McCULLOCH CO., Limited, Galt, Ont.—

Dear Sirs:—Answering your letter of February 5th, regarding the type "H" Water Tube Heating boilers which have been recently installed at the Ottawa Collegiate Institute, I beg to state that these boilers have been in operation since the beginning of the winter and are giving entire satisfaction. I made inquiries to-day as to how they were working and Mr. Pearce reported that they were doing fine. As you are aware this was an exceptionally cold morning and it is a pleasure to know that we have a heating plant that can handle everything it is called upon to do without trouble.

This type of boiler we find to be a very fast steamer, so that the fireman can heat the building very quickly at any time when the fire happens to go down.

I should be very glad to recommend this type of boiler to any of your clients. Yours very truly.

J. A. EWART.

NOTE: Tuesday, Feb. 6th, 1923. The morning referred to above, temperature registered 24° below zero.

How Ball Bearings Can Reduce Transmission Costs

Development of Ball Bearings for Lineshafting—Save 20 to 30 Per Cent. of Total Power—Cut Lubrication and Maintenance Bill 80 Per Cent.—Various Types of Drives

By R. C. HAWKES

IT SHOULD be quite unnecessary to commence this article by advancing proof showing that ball bearings reduce transmission costs, as everyone is familiar with the results that have been obtained with the use of ball bearing hangers for some years past, but it might be desirable to briefly outline the present day ball bearing and the difference between it and the original bearing with which the reader may have had some unfortunate experience. An entirely satisfactory ball bearing was not developed until about ten or fifteen years ago. Previous to that time several types of bearings were put on the market, but they were mostly designed along the lines of the bicycle ball bearing and would only operate satisfactorily under light loads at slow speeds, with the shafting absolutely in line. A bearing with these limitation is no use for lineshafting where belts are sometimes tightened almost to breaking point, and where mis-alignment is always present.

Load Factor

The bearing of to-day is quite different. In designing the modern ball bearing for transmission work, a load factor considerably in excess of the breaking strength of the shaft itself is used. The bearings are proportioned in this manner: take any size shaft, say 2-7 16in. for illustration, support it at points eight feet apart. Then at a distance of four feet from either support, weight the shaft down until failure occurs. This breaking weight is then noted, and the thickness of the metal in the inner and outer rings of the bearing together with the diameter of the balls is calculated to withstand three times this breaking strength of the shaft itself; therefore in order to crush a ball or fracture a ring, a pressure three times greater than that required to actually break the shaft would have to be exerted on the bearing; a condition which could only be brought about by either wilful destruction, collapse of the bearing or impact of a flying piece of broken machinery.

In addition to this, the modern bearing is self-aligning, so will continue to operate when the shafting gets out of line without increased friction or wear and without heating. As it is generally impossible to keep shafting in line through foundations settling, loads being placed on the upper floor and other causes, the self-aligning feature is essential. The speed difficulty has also been overcome, as will be shown later by the fact that shafting is being run in ball bearings with absolutely no trouble at 1,000 r. p. m. This would be impossible with babbitt bearings. The self-aligning and other features of the modern ball bearings are illustrated in Fig. 1.

Savings in Lineshafting

Coming to the subject of this article, the old method of driving machines naturally receives first attention. Under the old method a main shaft is run down the centre of the machine room and the machines driven from it by belts through the medium of countershafts. This system wastes a great deal of power, as from 40 per cent. to 60 per cent. of the total power consumed by machines and shaftings is used to drive the shafting, so only from 60 per cent. to 40 per cent. of the total

power is actually delivered to the machines. This statement is substantiated by Kent's Engineers' Handbook. Shafting running in ball bearings will run at least 80 per cent. easier than in babbitt bearings, so will therefore save anywhere from 20 to 30 per cent. of the total power used.

In order to obtain some accurate figures on lineshaft bearing friction, the University of Wisconsin some time ago conducted tests which extended over a period of four years. It was decided that where a shaft running on ball bearings takes one unit of power, the same shaft on roller bearings takes from 2.2 to 3 units of power, and the same shaft on babbitt bearings from 3 to 4.5 units of power.

Annual Lubrication

Besides the power saving, ball bearing hangers make a big cut in the lubrication and maintenance bill, as it is only necessary to lubricate them once or twice a year, depending on the speed, with vaseline or a special ball bearing grease. This means that the oiler can be eliminated and the man be given some other work where he can produce. Also rebabbitting becomes a thing of the past, as do shut-downs through hot bearings. A properly designed and made ball bearing will last indefinitely.

Several large installations have been in operation in this country for over ten years, and the bearings show no appreciable sign of wear, and there is every reason to believe that they will run for at least another ten years. This should be all that is necessary to overcome the arguments of some of the older school of mechanics who claim that a serious drawback of the ball bearing hanger is that when the bearings fail they cannot be removed from the shaft and replaced as easily as babbitt bearings, because ball bearings are not split. They don't have to worry about that, when the ball bearings run for at least ten, and probably twenty years without requiring repairs.

Factor of Cost

A very recent example of ball bearing money saving was noted in Sherbrooke, Que. In a small planing mill the babbitt bearing hangers on the main shaft were thrown out and replaced with ball bearing hangers which cost $178.00. The proprietor reported that his power bill was reduced by $5.00 per month, and that he estimated he was saving about $4.50 in oil and time; also count about $50.00 per year for rebabbitting, making a total of $164.00 per year. Even if the rebabbitting charge is left out, he would still be saving $114.00 per year, which would represent a return of about 65 per cent. per annum on his investment. Very few propositions can show such a high return as this.

Overloaded Motors

Here is another opportunity for ball bearings to cut transmission costs. When the plant engineer or superintendent is confronted with the fact that a motor driving a group of machines is overloaded and the shafting is running in babbitt bearings, he can take one of two courses to remedy the trouble. He can buy a larger motor, or change the hangers and install ball bearings on the shafting. If he puts in the larger motor, which will cost a considerable amount of money, as much, or more power will be used than before. Also very little will be realized by the sale of the old motor. If ball bearing hangers are installed, however, a large power saving is effected, thus cutting the power bill, the overload condition is remedied and the old motor still used. This happened some time ago in Kitchener, Ont. In one of the plants there a 40 h. p. motor driving a line of machines was so much overloaded that it was heating badly, and the superintendent was hourly expecting it to burn out. He called in a well-known firm of anti-friction engineers, and they changed over the hangers on the lineshaft to ball bearings. Later, power tests were made, and it was found that only 30 h. p. was being used, so the ball bearings saved 25 per cent. of the power on the motor rating, plus the overload.

Group Drives

There is no doubt but that the group drive system is the most efficient in every way. In some cases it is not possible to so arrange the machines that this system can be used, but this does not happen often, so it will be found that in most of the plants which have been built or remodelled during the last few years, the machines are grouped, each group being driven by a separate motor. Here ball bearings play a big part. By running the short shaft, used to transmit the power to each machine in the group, on ball bearings, the shaft can be run at any speed up to 1,000 r. p. m.

It is then possible to drive directly down to the machines and eliminate countershafts. Also, owing to the high speed, the size of the pulleys on the shaft would be reduced. This in turn increases the speed of the belts and as a belt will transmit more horse power the faster it runs, lighter and narrower belts can be used. Thus by using the group drive system and running the shaft in ball bearings, such savings are made in counter shafts, pulleys and belts, that the initial outlay is less for ball bearings than for babbitt bearings, with the ball bearing hangers costing three times as much as babbitt bearing hangers. Then, of course, the power and maintenance bill is reduced as with the long lineshaft.

Another advantage of running the shafting at a high speed, is that the motor can be connected directly to the shaft by means of a flexible coupling, thus eliminating the drive belt and leav-

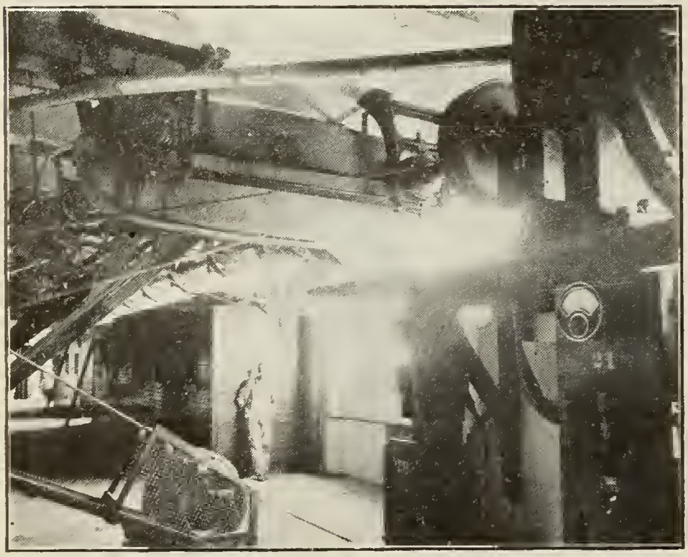

Fig. 3—Installation in Quaker Oats Plant at Peterboro, Ont.

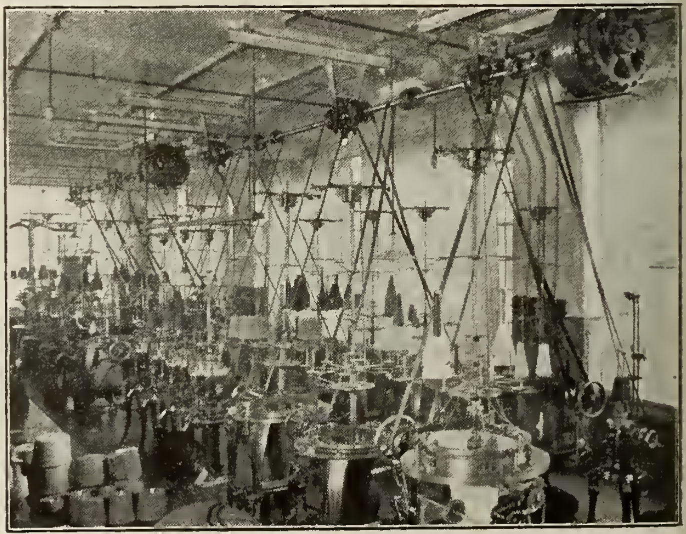

Fig. 4—Group drive in T. Eaton factory at Hamilton, Ont.

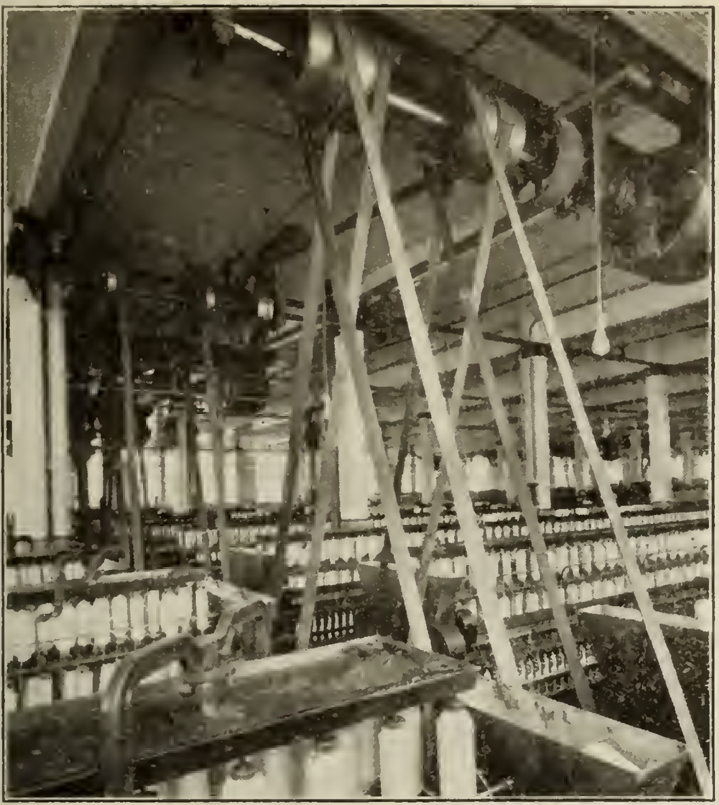

Fig. 2—Spinning frame drive in plant of Manhasset Cotton Co., St. Hyacinthe, Que.

ing that space which would have been taken up by the belt, available for other purposes. A good example of this type of drive is shown in Fig. 2. This is the spinning frame drive used throughout the plant of the Manhasset Cotton Co., St. Hyacinthe, Que. A 30 h. p. motor is directly connected to a short shaft which is driven at 900 r. p. m.; a belt drives a parallel shaft of about the same length. Six spinning frames are driven by each motor.

Typical Installation

Fig. 3 shows another instance where the motor is connected directly to the shaft. In this case the motor is 400 h. p. and the shaft size 4-15/16in. dia., running in ball bearing hangers. This installation is in the Quaker Oats Company's mill at Peterboro, Ont.

Fig. 4 shows another group drive installation in the T. Eaton Company's knitting factory at Hamilton, Ont. Again in this case the motors are supported from the ceiling, and do not take up any floor space.

In each of the above plants it is important that no oil be allowed to drop from the hangers onto the material in process of manufacture. The ball bearing hangers are absolutely clean. Grease is used as a lubricant and this is retained in the bearing housings by felt washer seals, and unsightly drip pans are not required.

Another instance where ball bearings made it possible to run the shaft at a high speed and eliminate countershafts, was found a year or two ago in a silverware factory where two rows of buffers were installed. Here a shaft about 22 feet long was mounted in self-aligning ball bearing hangers which were bolted to the floor. The shaft was driven at a speed of 1,000 r. p. m. The buffers were mounted on a bench built over the shaft and were driven from the shaft by light belts. This made a very simple and satisfactory layout, and money was saved on the initial cost, as if babbitt hangers had been used it would have been necessary to have used a countershaft for each buffer.

Efficient System

The group drive system has generally proven to be more efficient and economical than direct drive where an individual motor is used to drive each machine. In the first place the initial cost of a motor for each machine is naturally very high. Then smaller motors are required than would be used to drive a group of machines and it is well known that the smaller the motor, the less efficient it becomes, so that a great deal of power is wasted by a number of small motors. Also the upkeep of the motors must be considered. A fair sized plant would use several hundred motors on the direct drive system, and it would be necessary to permanently employ a staff of electricians to take care of them. With the group drive system a few motors of at least 25 or 30 h. p. are used, and the efficiency of a motor of this size is quite high compared with motors of one or two horse power.

It will be seen from the foregoing that there are many ways in which ball bearings can reduce transmission costs, so much so that the ball bearing question should be gone into very thoroughly when considering a new installation or contemplating alterations to an old one. The best way is to consult a reputable ball bearing company that can offer an engineering service, and obtain their engineers' opinion and suggestions.

Water and Tidal Power

In his recent presidential address to the Newcastle-on-Tyne Association of the Institution of Civil Engineers, Mr. R. F. Hindmarsh, M. Inst. C. E., Chief Engineer to the Tyne Improvement Commission, took for his subject "The Utilization of Water and Tidal Power." In the course of his remarks the President said that water wheels were in use 3000 years ago on the Nile, and that similar wheels continued in use without improvement until the early part of the eighteenth century; wheels turned by tidal currents had also been used in this country and in America, Spain and France, but on account of their insignificant magnitude and primitive design, and also to their intermittency, these were not suited to the ordinary industrial uses.

The water turbine was evolved in 1823 by a Frenchman, and such machines were capable of developing much greater powers and of operating at higher speeds than the old water wheels which they gradually displaced, although in some places water wheels were still doing useful work. Recent improvements in the water turbine and electrical appliances had made possible the great advance which had been made in hydro-electric work in the last few years. The total potential water power in the world was, said Mr. Hindmarsh, estimated at 200 million horse-power, but so far only about 25 million horse-power has been utilized. It would, however, take the whole output of the mines of the United Kingdom to produce as much energy as it at present produced from water in the world. The United Kingdom at present only developed about 200,000 horse-power from water power, and had not nearly the resources of many other countries, but there were still possibilities of much further development, especially in Scotland, it being estimated that energy could be developed at an economic rate from certain undeveloped water power resources nearly equalling the amount developed at Niagara Falls or an amount equal to the power generated in the 410 public steam power undertakings for electric supply to railways and tramways in Great Britain.

Although deficient in inland water resources, the motion of the tides around the coasts of this country represented, continued Mr. Hindmarsh, an enormous possible source of power, the western and especially the south-western coasts of Great Britain being particularly suit-

New Developments in Smokeless Combustion

Means of Utilizing the Heat of Generation to Consume the Heavy Gas Products—Thorough Mixing of Heated Excess Air With Volatiles Promotes Better Results

By H. M. NOBIS

COMBUSTION is said to be complete when the combustible elements have united with all the oxygen with which they are capable of entering into a combination, provided the ignition temperatures are high enough.

It would be foolish on my part to claim a perfect combustion in a heating boiler, but we certainly should strive to have a complete combustion. While combustion is complete but not perfect, there are losses due to excess air and it follows that the more nearly complete combustion can be made to approach perfect combustion, the less the loss that will occur in the burning of any fuel.

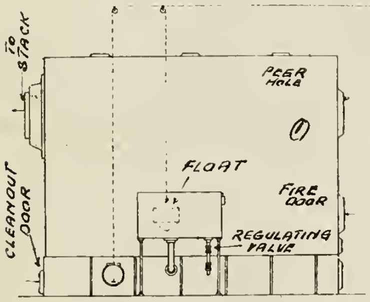

Fig. 1.—Automatic air control for single grate boilers.

The majority of the schemes employed for smokeless combustion consists of admitting excess air before, above, behind and through the bridge wall. It is a debatable question with some engineers where the proper inlets for the air supply should be located and where the contact point between the gases and air should occur. However, I express my firm opinion that the air inlet should be above the fuel bed, no matter what type of heating boiler is used. The air inlets should consist of openings with shutters which could be closed after the smoke is burned off. In ninety-nine cases out of one hundred, this is not done and, as the heavy smoke burns off in about fifteen minutes and the average firing period is two hours, the cold air may do more harm than good.

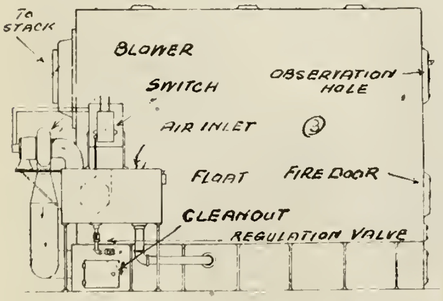

Fig. 3.—Blower type of automatic air control for sectional cast iron boiler, arranged for smokeless combustion.

My experience is that it is easier to prevent smoke by manipulating the fire door, giving a large amount of air at first, gradually diminishing and then closing it off entirely. As all the abovementioned air inlet methods produce a delayed combustion in the boiler flues and chimney, the writer has compiled the following rules to achieve a good and smokeless combustion:

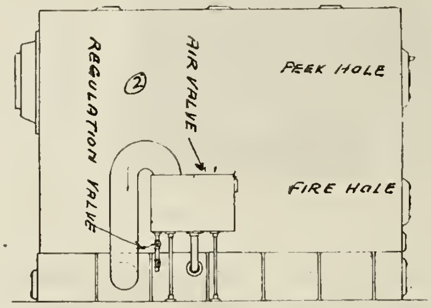

Fig. 2.—Automatic air control for sectional cast iron boiler arranged for smokeless combustion.

Suggested Rules for Smokeless Combustion

1. The introduction of hot excess air above the fire, first in large quantities, gradually dimishing, and shutting off entirely in 10 minutes.

2. Methods to compel a thorough mixing of the heavy smoke with the heated excess air above the fire, allowing a certain period of time to complete the consuming of the heavy smoke.

3. The presence of heat-storing materials which absorb a part of the high heat generated during the smoke-consuming period above the fire, which storage heat may be used to ignite the lighter combustible gases.

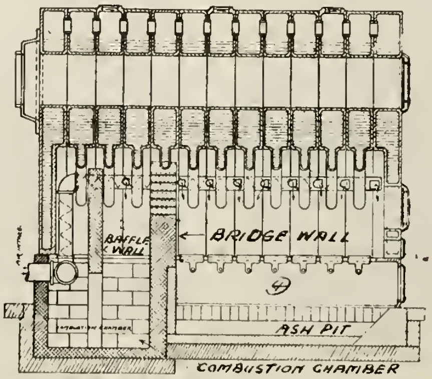

Fig. 4.—Sectional cast iron boiler arranged for smokeless combustion.

4. Means to insure a thorough mixing of these lighter gases with the unavoidable air inleakage along grate supports, fire holes, doors, etc.

Acting on these principles the writer constructed an apparatus shown in the accompanying illustrations which he installed in a 36-series, 9-sectional National Radiator Company boiler. The coal burned comes from a Belmont County (Ohio) mine containing about 39 per cent. volatile matter, 47 per cent. carbon, 4 per cent. sulphur and 10 per cent. ash, having a heat value of about 12,900 B. T. U. This coal is burned on 15½ sq. ft. of grate surface, with draft produced by a chimney 18 in. x 18 in. x 55 ft. high. The direct radiation attached to the usual vapor system piping is in excess of 4,000 sq. ft.

To fulfill the principle of the first requirement, we installed 4-in. heavy cast-iron piping on both sides of the furnace. These pipes are supported by the extended water tubes found in these boilers. The method adopted for introducing the excess air is shown in Fig. 3. This apparatus consists of an enlarged toilet tank, the water contents being discharged into the ashpit before the fireman begins to add fuel or stoke the fire. The copper float sinks with the water level, closing an automatic float switch which supplies current to a direct-connected blower, as shown. The air discharge is connected to the 6-in. cast-iron pipe leading inside the furnace. An orifice in the city water supply line to the flush tank fills the tank in from 10 to 20 min., lifting the float which breaks the current to the motor. The partition of the tank being submerged partly in water closes the air inlet to the blower. The partition is made with a V-cut opening, diminishing the air supply gradually during the blower operation, giving a large amount of excess air at first.

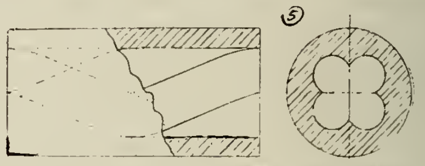

Fig. 5.—Fire brick for furnace bridge wall.

The second requirement is solved in the following manner: The outlet openings in the blower discharge pipes inside the boiler (Fig. 4) are slanted sidewise so that the escaping air stream blows against the fuel bed. The max-

(Continued on page 27)

Means of Measuring Capacity of Refrigeration

Value and Use of Instruments in Analyzing the Operation of a Complete Refrigeration Plant, With Comment Upon "the Unit of Measurement" Used on Gauges

By JOHN E. STARR*

IT HAS always seemed to the writer that the proper way to regard a refrigerating machine is from the basis of the number of pounds of liquid that heat applied at a low temperature will evaporate or boil into a gas under certain given conditions of pressure. So much for capacity.

For efficiency the calculation would be the number of pounds it will condense back to a liquid under certain conditions of pressure and temperature. There is, of course, nothing new in this statement of the case, except that it is an indication of a more simple attitude of mind in approaching the subject and getting a proper perspective of the process as a whole.

Instruments that will measure the steps of this operation are necessary to use in order that we may properly control the steps and have knowledge as we proceed that we are proceeding properly. It is, therefore, of the utmost importance that we know the weight or the number of pounds of liquid circulated per unit of time, for in any liquid whose physical properties are well known, such as ammonia, if we know the temperature at which it is fed to the boiler and the quantity boiled by our refrigerating temperatures in a unit of time, we know the amount of heat taken up. To this end I would regard the instrument showing the temperature of the liquid just before passing the expansion valve, or the liquid thermometer, as the most illuminating instrument of capacity measure. Coupled with this an accurate instrument for showing the pressure at which the liquid is boiled is, of course, necessary, also an instrument showing the number of pounds per unit of time.

Having accurate instruments to show these three conditions the actual capacity is quickly, easily and accurately determined. Where brine is used as a heat carrier, a check can be made but it is hardly necessary, as the before mentioned method of arriving at capacity has proven satisfactory within a small per cent. of calculation from the brine and is imperative in direct expansion work. It follows the very familiar routine of calculation of steam boiler efficiency and capacity, for if we know the temperature of our feed water the pressure of our boiler and the pounds fed to it we are in a position to calculate exactly how much heat is put into it.

An oil filled well on the feed line about one and one-half or two feet before the expansion valve and an accurate glass thermometer can be made to give an accurate record. An accurate recording thermometer can also be used, subject to the usual objections here mentioned attending the transfer to the record (which is, perhaps, less liable to error in thermometry recording than some other recording instruments).

Mercury Pressure Gauge

For a pressure instrument for such low pressures as usually obtain in refrigerating work a mercury pressure gauge will prove on the whole more accurate and less liable to get out of order and frequent readings insure a reasonable average. Sometimes an accurate recording gauge is found that will give results comparable to a mercury gauge and although the readings are necessarily coarser they may be sufficiently commercially correct. On the whole a mercury pressure gauge is preferable as giving surely accurate results and a fine scale. For measuring quantity, the Venturi meter has been perfected so as to give results from one to three per cent. of calculation by brine load with the chances for this small error all in favor of the meter, but in any event commercially close. The writer would not hesitate to assign capacity from data obtained from the weight, temperature, and pressure of the liquid used and would feel particularly safe with ammonia, the properties of which are almost as well authenticated as those of water.

Considerations given above, of course, cover capacity. The burning question of H. P. per ton requires a different set of instruments.

Where Electricity is Used

Fortunately where electricity is used for conveying power a direct relation can be almost instantly established between H. P. and capacity and if such results are satisfactory and as good as the best nothing more need be investigated. A reliable ammeter and volt meter, checked with a reliable wattmeter, which can be supplied by any reputable electric concern, gives with the calculation of capacity the proper figures for H. P. per ton.

These instruments, of course, should be checked occasionally for accuracy the same as one would check any other instrument of accuracy.

To insure that the condensing process is being properly conducted and as a guide to operation a number of instruments of measure are employed, and all should be of the best—for it must be always kept in mind that a lying instrument of measure is worse than none at all.

Pressure Gauges

For every day convenience a pressure gauge to register the back pressure and one to register the head pressure are placed in plain sight of the operating engineer. If an accurate mercury gauge is used as before mentioned (for the purpose of closely estimating capacity), the working gauge should be compared to it from time to time to insure that it keeps fairly accurate. For head pressures, reliance is usually placed on the working high pressure gauge and insurance of its accuracy should be had by periodical accurate tests. The temperature of the liquid thermometer is the guide of pressure. It is recommended that a separate scale be added showing corresponding saturated temperature.

The head pressure shown by the head pressure gauge in most instances should not be more than eight or nine per cent. numerically greater than the pressure called for by the temperature of the liquid and sometimes runs even closer. Perhaps with very high head pressure it might run a little more but a difference of ten or twelve pounds is commercially attainable.

If it is farther away than this, it is time to look for foul gas in the condenser surfaces or insufficient surface.

An indication of any particular make of gauge would be out of place here, as there are a large number on the market. But be sure they are reasonably accurate.

For complete information, a thermometer to record the temperature of the compressed gas as it leaves the compressor is desirable. It is impossible to expect that it will indicate accurately the state of the gas immediately when it has reached full compression, as many heat transfers may happen before the compressed gas reached the thermometer, but these thermometers may indicate that it would be well to more intimately examine the compressor and a "stitch in time" may be taken, on the gentle hint that may be given by this instrument. It may show a temperature so at variance with the calculated outlet temperature, notwithstanding jacket influence, if there be any, that an examination by use of an indicator may be called for.

The Indicator

Of the use of the indicator and the lessons to be drawn from its use one cannot do better than refer to Mr. Voorhees' little book on "Indicating the Compressor" where the subject is treated simply and to a much greater extent than can be allowed in the scope of this paper.

The indicator is an X-ray photograph of the interior of the compressor in action and a sure exposition of its faults, if any it has, and a suggestion of cure.

For commercial convenience the volumetric efficiency of the compressor is often referred to as the relation of its swept displacement (clearance considered) to the evaporative volume. This is really what we desire to know in the final analysis from a commercial standpoint, but taken alone is not always fair to the compressor. Therefore, to get at the real facts affecting compressor performance a thermometer on the suction near the inlet valve is desirable.

A whole lot of things might happen to the gas on its way from the boiler to its arrival at the suction valve and inevitably it might occupy a much larger volume per pound by the time it reached the suction valve over its volume per pound at the evaporator. If the difference is only seven or eight degrees we might commercially neglect it, but if it runs large it is unfair to charge against the compressor acquisition of heat that has probably done nobody any good. The heat so acquired has, in all probability, not come from the brine or any other place where its removal benefits anyone.

The heat that is thus unprofitably taken up between the evaporator and the suction valve has, of course, to be raised to a higher plane and eliminated just as if it had done useful work and represents, therefore a dead loss.

To keep track of this loss so that if possible a means can be devised to prevent it, at least partially, it is desirable to place a thermometer where indicated as showing the temperature of the suction gas when the compressor takes hold of it and compare with the evaporation temperature. Differences of 20 to 25 degrees are not uncommon and this means an appreciable increase of volume and its amount can be estimated in dollars and cents.

Recording Gauges

Recording gauges (except perhaps temperature recorders) are very apt to get out of order and to present lying information on their charts. The trouble is not in the instrument that gives the information, but in the mechanism that attempts to convey this information to a chart. If the error is a constant one, the chart if not valuable for specific information as to the true state of affairs at any one time, may be valuable for qualitative analysis or comparison, but unless one is very sure of the accuracy of the transmission it is perhaps doubtful if the charts will form a correct basis of estimate. Original readings of the original accurate instruments are better and surer, especially in a test, and a person making frequent readings often sees things that a chart will not tell him.

As a result of many tests the writer feels almost safe in relying on the amount, temperature, and pressure of the working fluid as a measure of capacity, but many plants are equipped for measuring capacity by quantity and temperature of brine, which is of course a reliable method in itself, and also gives opportunity for a check on the other method. Both methods are, of course, subject to another check by calculation of gas volume. Aside from estimation of tonnage and H. P. per ton it is desirable to keep track of the temperature and often the quantity of brine. Sight thermometers of the separable socket-type are made that are closely accurate, and, if the expense is warranted, there are pretty reliable recorders on the market. A continuous record is of use to the engineer, and especially of value to the managers. Care in placing them is, of course, to be taken to insure that they give the average temperature of the brine.

As to the brine meters, it can probably be said that there are few recording brine meters that can be absolutely relied on. A Venturi type of meter, carefully calibrated for the density of brine employed and the average temperature, would be considered accurate if original readings of pressure differences were taken at the meter tube, but a great chance of error lies in the transmission to the integrator and chart. Measure by pump piston displacement with allowance for slip as shown by calibration by a measured test at the same temperatures and pressures, is perhaps as reliable as any method and is usually convenient as the brine circulator is also the meter. Record of specific gravity is better taken by a hydrometer with a widely marked specific gravity scale than by some arbitrary scale as the salometer or Baume hydrometer. Errors and time in translation are thus avoided.

Checking Efficiency and Capacity

Measurement of inlet and outlet temperature of condensing water and weight of same is, perhaps, the quickest and surest way of arriving at efficiency and checking capacity. Where a water pump is used, an occasional calibration by discharging into a tank where known weight or volume can be easily ascertained is desirable and a well placed inlet and outlet thermometer completes the data. A check on the capacity and reasonableness of the H. P. per ton is instantly made by this method.

The working of the condenser is also quickly arrived at.

The head pressure should show a corresponding temperature very close to the temperature of the hottest or outgoing water.

Of the tests shown by Denton in Kent's book:

No. 1 showed 1.09 degrees condenser temp. over hottest water.

No. 2 showed 0.3 degrees condenser temp. under hottest water.

No. 3 showed 2.26 degrees condenser temp. under hottest water.

No. 4 showed 5.79 degrees condenser temp. over hottest water.

Three tests by Horne showed condenser temperature 7.8 degrees hotter than hottest water on the average.

Four other tests by Horne with colder water showed an average of 10.6 degrees hotter condenser temperatures than hottest condensing water.

As a general rough rule one should be pretty well satisfied if the temperature corresponding to condenser pressure is say, not over five degrees above the temperature of the hottest or outgoing water. He should congratulate himself if it was nearer or under and in summer weather should look to his condenser conditions if it showed more. The heat of the liquid might show in some condenser of the double pipe type as very near or even fully as cold as the coldest or inlet water. For a few degrees difference either in condensing temperature or heat of liquid the final item is small but is worth attention.

The reasonableness of the figure obtained for capacity is also easily checked by this method. For example, if the reputed tonnage or tons shown by test per minute are divided into heat per ton per minute removed, as shown by the condensing water, the reliability of the tonnage data may at once be shown to be ridiculous. Tests have been made where the heat out by water showed less than 200 B. t. u. per minute. As the heat added per ton is 200 B. t. u. per minute the water test must have been wrong or else the tonnage calculation was wrong. Or suppose that a machine at 180 lbs. head and 20 back showed only, say, 230 B. t. u. of heat removed by condenser per ton per minute. It is clear that 200 B. t. u. must be only 30 B. t. u. for heat added by power. A horsepower is 42.44 B. t. u. per minute. Hence the H. P. per ton on the gas would only show about .7 H.P.

Now common experience shows it would require about 1.2 H. P. on the gas under these conditions of pressure in a simple compressor. Hence the only conclusion is that water measurements of quantity and temperature were wrong or else the figures for tonnage and H. P. per ton were wrong. If the I. H. P. of the compressor was not taken on the test it is easy to approximate it by its usual percentage of H. P. in at the engine or on the wire. Eighty per cent. is close enough. So figures obtained from thermometry and quantity of condensing water are of immediate and great value. The measurement of heat out is equivalent to the measurement of heat in. Absolute fine correctness is little disturbed by reception or loss of heat from the atmosphere in machines over 5 tons in capacity.

The heat influx to and outflow from the apparatus is seldom calculated at much more than three per cent. of the entire amount accounted for.

In the Horne test of Oct. 21, 1922, which was a very careful one, the heat out was calculated at 27.2 B. t. u. per ton. The available heat in for refrigeration was, of course, 200 B. t. u. per ton, leaving 72 B. t. u. for power or

$$\frac{72}{42.14}=1.68 \text{ H. P. on gas.}$$

The actual I. H. P. on gas was shown to be 1.666, or an agreement of less than one per cent. Numerous other good tests show results nearly as satisfactory.

Scaling of Gauges

Here opportunity is taken to register again the century old protest against the scaling gauges. Why use an artificial scale on any instrument? Why not use a specific gravity scale or a hydrometer? Specific gravity is what you want to use finally. Why use some other scale? And then hunt up a table for translation and lose the time and run the risk of making an error. Why do not our pressure gauges tell the literal truth and when we have a real pressure of 35 lbs. why do they read 20.3 lbs?

Even our manufacturers of CO_2 gauges habitually give their record in atmospheres above the atmosphere and when they say 20 atmospheres they really mean 21 atmospheres or when their gauges read 64 atmospheres for head pressure it really means 65 atmospheres.

Only the other day the writer, who has devoted some thought to methods of making things plain, found it difficult to convince a life long ice manufacturer that 30 lbs. gauge represented 1½ times the pressure of 15 gauge instead of twice the pressure as the old-timer's habit of thought had fixed in his mind, and while the writer was able on logical grounds to explain step by step the true meaning of absolute pressure, gauge pressure, and inches vacuum it was apparent at the end of the discussion that while the old-timer was amenable to logic he was hazy on the results as a whole and still clung to his lifetime habit of thought. How few of us could offhand, and without considerable mental effort, state the relative pressure of 21.78 inches of vacuum and 25.85 inches, except to say it represented a difference of 4.07 inches? If the correct expression was used, to wit, the difference between two and four pounds, the mind would at once perceive that twice as much pressure was involved in one case over the other. Or if the smaller unit and coarser scale of pressure was used (omitting decimals) of four inches mercury pressure and eight inches mercury pressure how quickly the mind would appreciate the numerical magnitude of two to one. The present method of scaling gauges with the zero at a point that only exists in nature in limited areas of the globe is responsible for the universal idea in the minds of many that a vacuum does something, which is quite different from the true statement that if a vacuum or less pressure is created something may be done. Why not have our gauges convey the literal truth and start the zero at the true zero?

The same might be said of thermometry. Why should not our thermometers be gauged numerically so as to tell the direct truth? Instead they oblige us to get at the truth by a more or less laborious process of figuring.

Owing to habit it might take some time before the world at large would appreciate that say 520 F. meant the same degree of heat as 60 F., but why oblige one to consider 460 and add or subtract 460 almost every time he wants to make a calculation that will get him anywhere? It is true that there is an infinitely small error in placing our absolute zero, but it is too small to affect any practical end and we might just as well regard our freezing point of water of 492 as an incident to be classed with the freezing point of other fluids instead of a starting point as in the centigrade scale or the rather clumsy expression of 32 degrees more than our F. zero or starting point.

If we cannot have a universal spoken language we may have at least a universal technical language instead of confining it to the small word of technicians.

This article confines itself closely to a discussion of instruments used in analyzing the operation of a refrigerating machine and does not attempt to discuss instruments dealing with the production of motive power except in the mention of delivery of power by electricity.

NEW DEVELOPMENTS IN SMOKELESS COMBUSTION

(Continued from page 24)

imum amount of the air is released at the pipe ends blowing across the fire door, preventing to a certain extent, the inrush of cold air as the fireman starts the blower before the fuel charge. This forced-in air creates above the fuel bed a very lively commotion, burning the soot and smoke above the fire and not in the flues.

Introducing the heated air above the fire checks, to a certain extent, the rapid flow of air through the fuel bed, retaining the combustible gases, such as methane, ethane, acetylene, etc., within the fuel bed, these being burned off later on.

The partitioned-off bridge wall prevents the rapid flow of the smoke which is given time to burn above the fire, thus developing a high temperature at that point.

The third and fourth principles are mostly covered under the second requirement, with the addition of utilizing the thread-like inside formation of the round fire-brick as a mixing medium for the gases. Fig. 5 shows the firebrick construction.

The above-described method has been found to produce very satisfactory results:

1. The smoke or soot is actually consumed, producing and maintaining exceptionally clean furnace walls and flues.
2. A higher temperature is maintained within the furnace, found especially after a banked fire.
3. A steadier steam supply.
4. Less and smaller clinkers due to the wet ashpit.
5. Clouds of light gray smoke, at first with a small continuous escape of vapor-like smoke curling from the chimney.
6. A saving in fuel.

Figs. 1 and 2 show the automatic arrangement which may be applied to single-grate boilers with side air inlets. The writer has developed a similar apparatus for use in firebox steel and return tubular boilers.

Helpful Advice Needed on Smokeless Combustion

Referring to the smoke ordinances of cities which permit only the use of down-draft boilers, these, in the writer's opinion, are laws which do not comply with the spirit of our Constitution. These laws should not stand in the way of improvements which are bound to come, nor should a community compel a man to burn a certain grade of fuel. What a community should do is to give to the plant owners, which emit objectionable smoke from their stacks, helpful advice. This helpful advice can be given by competent combustion engineers, but to the shame of our city governments, men with little knowledge of combustion principles in many cases, are appointed as chief smoke inspectors. Lack of finances is given as the cause for this condition. If every community with a smoke problem would have expended its money on real education, consisting of an appeal for cleanliness, the money expended would have been saved one hundred fold through the saving in trees, flowers, washing of buildings and in freight rates.

The law as it stands, operates only during the office hours of the inspectors. Everyone who is acquainted with large and small boiler operations knows that most of the objectionable soot is deposited on the damp and wet surfaces of buildings and vegetation, in the early morning hours.

The smoke and soot blown over a city in the morning does the real harm on account of the low furnace temperatures prevailing after a banked fire. These low furnace temperatures cannot burn the sulphur, etc., out of the flaky smoke, which will burn out of the fuel after the boiler capacity is reached.

The time is coming fast when certain steel-producing districts will be able to furnish coke at less cost than soft coal, owing to the valuable by-products gained. Lucky will be the owners who provide large coke-storing space, so that he may buy his fuel requirements during the summer months when great quantities are available at a reduced price. —"The Heating and Ventilating Magazine."

Proves Engineer May Aspire to Important Post

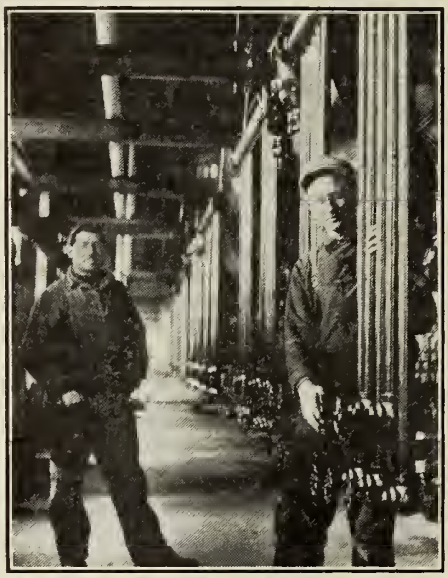
Fred Gonyou, Master Mechanic and Chief Engineer Dominion Sugar Co., Has Charge of Extensive Equipment—Responsible for All Buying—Says Technical Training Useless Without Ambition

IT IS not surprising to find Fred Gonyou, master mechanic and chief engineer, in charge of the mechanical and engineering departments of a $2,000,000 concern like the Dominion Sugar Company, Chatham, Ont., when it is found that he is the son of a master mechanic who spent some 54 years in the trade and is the brother of five licensed engineers. Fred Gonyou is a master mechanic and chief engineer by heredity as well as by practice—and his practice is of the most extensive nature.

Mr. Gonyou's start in the mechanical and engineering world dates back to the year 1879, the year after he had reached his majority. Born in Wallaceburg, Ont., he was a resident of that town until he was 22 years of age, and in '97 journeyed to West Superior, Wisconsin, to secure a thorough foundation in engineering in the employ of the American Steel and Wire Company of that city. Here he was engaged in overhauling the steamer "Empire City" and remained at work of this nature for a period of four years—four years of an apprenticeship which he considers was invaluable to his education. The end of the four years saw him stepping down a notch in the game signing on as a fireman on one of his company's ships which plied between the head of Lake Superior and Lake Erie and stopping at intermediate points.

When the winter had set in, Fred Gonyou went in for more practical experience. This time, his company placed him at the work of boiler making and tank building in their shops at Duluth and West Superior. He remained at this work until the year 1900.

The beginning of the 20th century found the Kilby Manufacturing Company erecting the large sugar factory of the Wallaceburg Sugar Company at Wallaceburg and also found Mr. Gonyou back in his home town helping with the construction of this plant and assisting in the placing of the multitude of machines which were soon turning out the finished product from the sugar-beet crop. The factory completed, Mr. Gonyou started on the ground floor in charge of the mammoth boilers. Six years spent in the Wallaceburg plant watched the young man move from the boilers to house foreman, from house foreman to machinist and, finally, from machinist to assistant chief engineer.



View of Battery of 12 Wickes Vertical Water-Tube Boilers, total capacity 4,000 h.p. During an operating campaign, eleven of the boilers work continuously at 120 lbs.

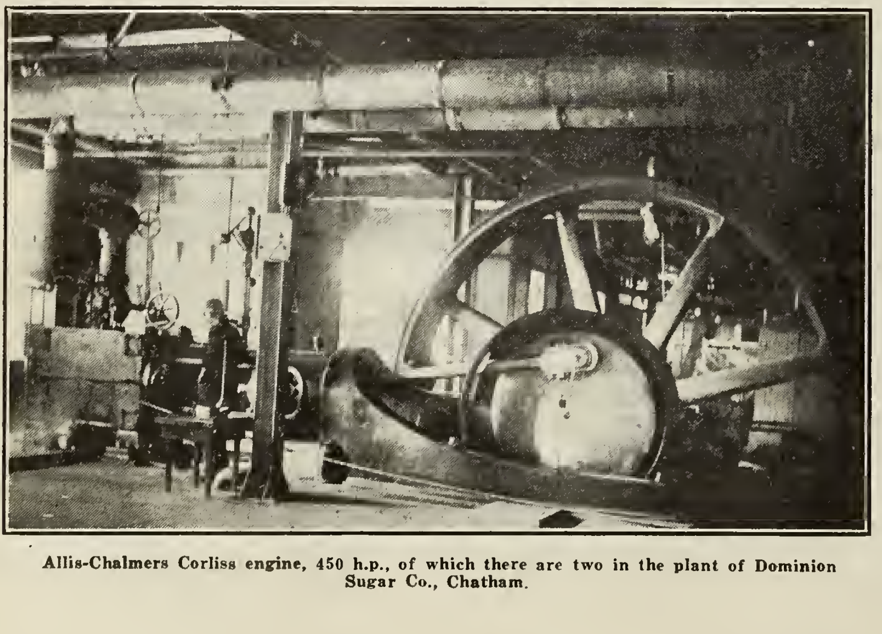
At the termination of his years in the Wallaceburg plant, Mr. Gonyou was sent by the Dominion Sugar Company to their plant in Kitchener to take the post of machinist and assistant chief engineer. He watched the old year out and the new year in, twice in Kitchener before he was sent back to his home town once more. This time it was in the capacity of master mechanic and chief engineer. Seven years spent in this capacity in the Wallaceburg plant, qualified him to take a similar position in the Chatham plant of the Dominion Sugar company. In this plant and in this capacity he has remained.

Mr. Gonyou's work in Chatham is very unique for a stationary engineer, and greatly exceeds the duties usually undertaken by a man of this position. He has full charge of all mechanical work in and around the factory which includes the mechanical work of a fleet of locomotives, locomotive cranes, tugboats and the machinery of the powerhouse and the main plant. In addition to this he has complete charge of all repair work and for this purpose he has under his jurisdiction fully-equipped boiler-shops, machine-shops and tin and pattern shops. His department does all of the machine repair work in this great factory and keeps the equipment in first-class working order. Mr. Gonyou states that this practice is very economical both in time and money.

Responsible for Buying

Instead of just operating and looking after the machinery as is the customary job of a stationary engineer, Mr. Gonyou is in charge of the general upkeep of the machinery in the entire plant as well as the tinsmithing and millwrighting. One remarkable feature of his position is the fact that he is responsible for practically all of the buying for his department with the exception of the coal. He is responsible for the purchase of all packing, belting, machinery and repair parts.

In combination with a large variety of powerful machinery, he naturally has a large staff of men under his supervision. The personnel of his staff consists, for the main part, of two assistant chief engineers with two assistants, eight station operators, a chief electrician and two helpers, one tin-and-coppersmith, a boss boilermaker and two helpers, three machinists, three carpenters and millwrights, two boiler-house



Allis-Chalmers Corliss engine, 450 h.p., of which there are two in the plant of Dominion Sugar Co., Chatham.

foremen, two steam tenders, eight firemen, four locomotive crane operators and locomotive engineers, a blacksmith, two factory oilers and about 15 labourers.

Power Plant Equipment

As for the machinery under Mr. Gonyou's control, one glance at the most important factors in the power-plant will give an idea of the responsibility resting on his shoulders. The powerhouse boasts of a battery of 12 Wickes vertical watertube boilers, with a total capacity of 4000 h.p. and a consumption of 225 tons of slack coal every 24 hours. The boilers are equipped with Westinghouse-Rooney vibrating grate stokers of 333 h.p. each. The main plant is driven by two Allis-Chalmers Corliss engines of 450 h.p. each, while the power for driving the machinery is generated by C. H. Brown engines connected direct to Bullock generators.

When the plant is working full capacity, eleven of the boilers are kept constantly at work under a working pressure of 120 lbs. of steam. The boiler house, as we might expect, is unusually well supplied with measuring and recording instruments, and with the various automatic devices, Mr. Gonyou states that the boiler room is practically under automatic control.

The Worthington feed pumps have a heavy duty to perform and are capable of pumping 60,000 lbs. of water against the boiler pressure, at a temperature of 210 degrees Fahrenheit in 24 hours. The lighting of the plant is provided for by a 200 h.p. engine connected direct to the generator. The plant in general is installed with the usual vacuum pans, pumps and usual equipment that are used in the process of the manufacture of sugar.

In the pump house there is a veritable battery of pumps, twenty-three of which are single acting reciprocating pumps, each having its own particular duty or function to perform in the process of sugar making. The fire pump is however, of a different class, it being a Worthington duplex reciprocating heavy duty pump, and evidently of a very large capacity.

Views on Technical Training

Referring to the grading of stationary engineers, Mr. Gonyou, who has been in charge of engineers and practical men for a period of 16 years, states that technical training is valuable, if it is not forced upon the machinist and engineer too aggressively. As a rule they have not the chance to accumulate the technical training asked for by examining boards. His idea would be to let the man with the practical education take a first-class trade journal or magazine for three or four years and then go in for technical work. This would give him a chance to understand just what is necessary and what the technical education means to him.

"In my estimation a thorough stationary engineer is one who understands everything in the manufacture of the product turned out by his company," said Mr. Gonyou. "For a man to stop at the work asked from a stationary engineer only means that he lacks ambition and is not the man wanted by the up-to-date firms."

Who could expect a man like Fred Gonyou to have any hobbies except those in connection with his work? He spends a great part of his time outside of the power house, in looking for improvements to his machines, money-saving devices and the general welfare of his men and his plant. That his men are satisfied with the conditions of the plant and the good-nature and manliness of their "boss" is evinced by the fact that he has two assistant engineers that have been working with him in Wallaceburg and Chatham for a period of 11 years.

Fibre in Metals

THE association of a fibrous structure with strong and tough materials, such as wood and rope, and the corresponding association of crystalline character with weak and brittle materials, such as sugar or bismuth, has produced in the minds of many men, and even of competent engineers, the conception that all really strong and tough materials must be fibrous, and that all crystalline substances are likely to be weak and brittle.

A study of their microstructure, however, shows, that all metals in a normal condition—i.e., when not severely cold-worked—are entirely crystalline, and that the minute crystals of which they are composed show no orientation of predominant length. There is, theremore, nothing in the nature of a "fibre" in the metal itself. The individual strips or bars into which a thick bar or plate becomes more or less completely divided by the presence of "slag" bands can never be any the stronger on that account. The metal itself, in fact, possesses no real fibre; its longitudinal strength appears greater than its transverse strength only because in the transverse direction the enclosure bands make their weakening presence felt far more actually than in the longitudinal. Were they entirely eliminated, the metal would be equally strong in all directions, and yet there would be no sign of "fibre."

It would thus seem that the desire for a "fibrous" structure is in essence a mistaken one, and that the cause of the fibrous appearance is in reality a weakness and not an advantage. It is true that under certain bending tests in which the power of the metal to undergo a large amount of plastic bending constitutes the main factor, the "fibrous" material shows higher results. Here the fibrous material gains a spurious advantage from the fact that it is enabled to behave very like a bundle of bars or thin plates rather than as a single piece of material. Owing to the weakness of the slag layers, the various rods and plates are approximately free to slide over one another and a large amount of bending occurs before fracture takes place. But this is no real gain for practical use. The Engineer (London), Nov. 10, 1922, pp. 499-500.

Meaford, Ont.—An offer of $35,000 was made to the town on January 31st, this year, for the power plant and lighting system of the Georgian Bay Power Co.

St. John, N. B.—Mr. C. O. Foss, chief engineer of the New Brunswick Electric Power Commission, recently stated that while the full development of the Grand Falls near the head waters of the St. John river, will likely involve international considerations, it is possible to develop some 60,000 horse power without having to tap any of the storage areas which lie in the state of Maine.

Corrosion and Oxidation of Iron and Steel

The Cause of Corrosion, Showing Some of the Earlier Theories Advanced to Account for These Phenomena—Composition of the Metal Has Much to Do With This Action

By T. S. FULLER

THE corrosion of iron and steel is a very old and broad subject, and one which has puzzled mankind throughout the centuries. It is because of this active tendency of things made of iron and steel to corrode and eventually to disintegrate that the early history of the metal is so much in doubt, and that it is so difficult to determine to what extent it was used by the ancients. The Pyramids of Egypt, which have been standing for five thousand years, were built of granite blocks probably hewn out with iron tools; and records show that during the blasting operations in one of the pyramids in the year 1837, a wrought-iron tool was discovered. Iron is mentioned in the Holy Scriptures in connection with the date 1200 B. C., and was known to the Chinese as far back as 2357 B. C. Probably the best known classical example of ancient iron, we are told by the General Electric Review, is the pillar standing at Delhi, India, said to have been erected in 912 B. C. Nevertheless, in the face of this evidence the early history of the metal is very much in doubt because of its disappearance through corrosion and subsequent disintegration.

For many years we of this country and the inhabitants of other countries have heard much of the so-called Conservation of Natural Resources, and of the substitution of materials which are found in large quantities for those which are less plentiful. May I ask what can be more important in the light of conservation than the saving of the materials iron and coal? When we consider that four tons of coal are required for the smelting of every ton of finished iron, and the coal supply in the United States is estimated to be sufficient for our needs for the next six thousand years, at the present rate of consumption, or for but one hundred and fifty years if the present rate of increase continues, the importance of the problem becomes immediately apparent.

To those of us who may not have been initiated into the various problems of corrosion, that yellowish-brown substance which forms when moisture is allowed to act on the surface of articles made of iron or steel is rust; and that is very often as far as our inquisitiveness takes us. To the person who has carefully observed and studied the mechanism of corrosion, the nature and the distribution of the rust are of the greatest importance.

But first let us consider briefly some of the theories which have been advanced in efforts to explain the various corrosion phenomena.

Corrosion was first considered to be a case of simple oxidation, similar to that taking place when iron is heated in air. It was soon discovered, however, that not only was the presence of oxygen necessary, but also the presence of liquid water.

This discovery led to the acid theory of corrosion, which takes into account the necessary liquid water and oxygen, and postulates, in addition to these, the presence of an acid, usually carbonic. The acid is assumed to unite chemically with the iron, forming a soluble ferrous salt, which is later oxidised to ferric hydrates or rust, liberating the acid radical for further attack upon the iron. By this method it is quite evident that very minute quantities of acid will be sufficient to cause corosion.

In 1903 Whitney announced the results of experiments which led to the electrolytic theory of corrosion. Distilled water was boiled in test-tubes to expel all the air and CO_2; polished samples of iron were added and the tubes sealed while the water was boiling. These tubes were left in this manner for weeks without the slightest appearance of rust on the surface of the iron or appearance of a corrosion product on the glass or in the solution. At the end of several weeks the tubes were opened and a small aomunt of air admitted. A precipitate of ferric hydrate quickly settled out. Dr. Whitney's interpretation of the results follows:—

Iron goes into solution in pure liquid water until the water becomes saturated with iron ions and a state of equilibrium is established. Until oxygen is admitted no precipitation of iron takes place. The conclusion is reached that iron goes into solution in liquid water in the absence of both an acid radical and oxygen, and that corrosion is, therefore, essentially an electrolytic phenomenon.

The hydrogen-peroxide theory postulates the presence of this substance as an intermediate product in the formation of rust, and the biological theory regards the corrosion of iron as a phenomenon due primarily to micro-organisms.

A brand new assumption in the list of corrosion theories is that recently announced by J. Newton Friend, presented at the last meeting of the American Electrochemical Society, and called by him an "auto colloid catalyaic theory of corrosion." Friend regards corrosion of iron as a colloidal phenomenon, corrosion taking place by alternate reduction and oxidation of ferric-hydroxide hydrosol.

Friend's theory is of too recent origin to have attracted a great deal of discussion at this time, and of the others only two—the acid and electrolytic theories—have been seriously considered by students of corrosion. It is a very difficult matter to say which of these two views is correct, because of the difficulty of getting extremely pure substances to work with, but the writer believes that it is safe to say that 90 per cent. of the students of the corrosion of iron prefer to regard it as an electrochemical phenomenon.

Considerable impetus was given to the study of corrosion by the experiments of Whitney, which led to the electrolytic theory. Later, Cushman and Walker developed a reagent which became known as ferroxyl indicator, which demonstrates quite clearly the nature of ferrous corrosion.

The indicator has been described in detail in a book by Cushman and Gardner, entitled "Corrosion and Preservation of Iron and Steel." Briefly, it may be prepared by mixing dilute water solutions of phenolphthalein and potassium ferricyanide. If a more or less permanent record is desired, the solution is thickened with gelatin or agar-agar. The action of the ferroxyl indicator is this: a solution containing phenolphthalein becomes pink in the presence of an excess of hydroxyl ions; potassium ferricyanide in the presence of ferrous ions forms the characteristic Turnbull's blue compound. Therefore, with the indicator in contact with an iron surface, the positive areas—e.g., points where iron is going into solution in the ferrous condition—are coloured blue, and the negative areas, where there is a predominance of hydroxyl ions, are coloured pink by these ions.

The writer suggests that those who are inclined to doubt the electrolytic nature of corrosion phenomena try a few experiments with the ferroxyl indicator. The results are startling.

The rate of corrosion of every piece of iron or steel depends upon the individual conditions existing in the particular localty in which the metal is in use, as well as upon the means which have been taken to prevent corrosion.

Bearing in mind that the two substances besides iron necessary for ferrous corrosion are water and oxygen, corrosion phenomena are of many types. Iron samples, wholly immersed, corrode faster if the water is moving rapidly than they do if it is in a state of rest. The rate of corrosion of iron tanks or pipes holding water is much less if they are kept full than if they are alternately wet and dry. Atmosphere corrosion proceeds much more rapidly in districts where the atmosphere is chemically polluted by sulphur vapors and the like, than it does in districts where the atmosphere is free from contamination. The corrosion of iron or steel is accelerated by contact with an element, such as copper or tin, electropositive with respect to iron, while on the other hand, corrosion is retarded by contact with an element more electronegative than iron, such as zinc. The corrosion rate increases with rising temperature.

The rate of corrosion is also dependent upon the character of the steel as determined by its chemical composition and heat treatment. Steel containing small amounts of copper or nickel resists atmospheric corrosion better than pure iron. The well-known stainless steels, containing large amounts of chromium, are highly resistant to corrosion.

The writer has found that much may be learned in a very short time about the corrosion-resisting properties of a steel by observing the action of a drop of water upon the polished surface of the metal. These experiments were described in detail before the meeting of the American Electrochemical Society in April, 1921, and will be briefly reviewed here.

Drops of distilled water in equilibrium with the air of the laboratory were placed upon various steel surfaces. In the case of pure iron, corrosion began almost immediately, and at the end of a few minutes the corrosion product could be seen distributing itself, always according to the same pattern. Three distinct zones developed: an outer one, which has been called by us the "immune" zone; an inner one, which occupied a large part of the area of the drop; and a "wall" zone, which lay between the outer and the inner zones. The outer zone was perhaps a half millimetre in width, and the wall zone was best described as a line. The iron rust was evenly distributed over the level on the wall zone, and the outer or immune zone was entirely free from deposits of any kind. Ferroxyl indicator showed pink over the outer zone, indicating a negative area, and that at this point no iron was going into solution, and blue over the inner zone, showing that corrosion was taking place over the entire central portion of the drop.

The length of time elapsing before the first appearance of rust, and the amount of rust present after the drop has evaporated, vary greatly with different steels and form the criterion for judging the corrosion excellence of the particular steel under examination by this simple test.*

Much has already been accomplished in the manufacturing of rust-resisting steels, or at least steels which rust less than pure iron, and much remains to be done. Examples are the steels containing chromium and the copper-bearing steels which have been mentioned elsewhere in this article. Of course, the ideal steel would be one having a low cost and showing no corrosion—a goal to be striven for, but probably never to be attained.

Protective coatings for iron and steel form an important section of metal technology. Various specially prepared paints are in use together with coatings of zinc, tin, or copper applied in different ways.

Of late, much has been said and written about the deactivation of water. In general, the scheme consists in passing the water to be used in a given closed system over scrap iron, to remove the dissolved oxygen. Once the oxygen has been removed, theoretically the water may go on circulating indefinitely in the system without corrosive action. Such installations have proved to be very successful.

Iron may be made immune to corrosion by making it cathode—that is, by making it the negative pole in a cell, with a potential just sufficient to balance the solution pressure of the metal. This method is not used extensively, because it is costly.

The general problem of corrosion is one which should be of the very greatest interest to all users of iron and steel —and that includes all of civilised mankind,—and it is most desirable that all should have as comprehensive an understanding of the subject as possible. There are many things which are as yet unexplained, but certain facts are so well established that they may be wisely borne in mind as follows:——

Two substances, water and oxygen, are necesary for the corrosion of iron.

The rusting of iron may be best regarded as an electrochemical phenomenon.

The rate of corrosion of every piece of iron or steel depends upon its composition, upon the means taken for its protection, and upon the individual conditions existing in the particular locality in which it is in use.

Much may be learned in a very short time about the corrosion-resisting properties of any sample of iron or steel by observing its behaviour under the action of a drop of water.

It is to be hoped that the efforts of those now at work on the various problems of corrosion, and the efforts of the investigators to come, will help to clear up the anomalies which yet stand in the way of a complete understanding of the subject.

WATER AND TIDAL POWER

(Continued from page 23)

able for tidal power development. A scheme had seriously been put forward recently for the development of power from the tides in the Severn, and the French were proceeding with the erection of a tidal power station near Brest at a cost of 28,000,000 f. The President referred to the many objections to erecting barrages in connection with tidal power schemes across navigable tidal rivers, and stated that it would seem necessary if tidal power were to be utilised to select places on the coast where navigation and other important interests would not be interfered with.

Few things were, he continued, more essential to industry and the welfare of the community than cheap power, and he therefore urged the necessity for engineers to give the question of utilising water and tidal power their closest attention. Coal was too valuable and would probably be too much in demand for other purposes to be burned under steam boilers if other economic sources of power were available.

REGULATING ELECTRIC PRESSURE

There is a multitude of forms of small plants for producing electric light by means of oil engines, but most of them are liable to a weakness which may under certain conditions prove rather troublesome. If the demand for electricity varies considerably—as it might do if the plant is driving a motor which is switched on and off—the electrical pressure will fall considerably. The engine governor is supposed to take care of this difficulty, but it does not always do so in time. A British firm has therefore devised a special pressure regulator which is suitable for plants up to about sixty horsepower. This regulator is so efficient that it will keep the pressure constant even if the governor on the engine is of a very primitive character. It is quite a simple little appliance and can be fitted to any existing machine.

A HUGE BRITISH TURBINE FOR CHICAGO

In 1912 the Electric Supply Undertaking in Chicago installed a British made steam turbine for the generation of electricity. This turbine was of 25,000 K. W., and was then almost the largest in the world. The results achieved by this British-made machine have been so satisfactory that the same undertaking has now ordered another steam turbo-generator of double the size from the same makers. This machine will be of record size and is confidently expected to maintain the reputation established for British electrical plant by its giant predecessor.

Somebody must pay for the conservation of the nation's human resources. If left to demand and supply, the most valuable resources are not conserved.

The Indicator

It has long been recognized by engineers that the error in a diagram taken from a high-speed engine with an ordinary indicator, is unavoidable due to the design of the mechanism. Of late years, this instrument has been receiving very close attention and every effort has been made to devise a means of overcoming the inertia due to the weights of the working parts. The error caused by this condition is one of the principal drawbacks in the design of this form of indicator and although the weight of working parts has been reduced to a minimum, the error cannot be totally eliminated. An electric indicator was invented a few years ago that very materially reduced the error due to inertia and although its advantages for high speed work are not wholly unrecognized, it was not found altogether suitable for ordinary use.

There has also of late been much attention paid to the optical indicator, which instrument very materially reduces the error due to inertia, and also totally eliminates the error due to friction caused by the movements of the pencil and piston. The price of this instrument, however, which is about five times that of the ordinary indicator, makes it prohibitive from a commercial standpoint, and, furthermore, the extreme delicacy of the mechanism and the heavy weight, makes it quite unsuitable for ordinary engine room use. These are obstacles of a very serious nature to fight against in commercial competition and it is therefore most unlikely that we will find an instrument of this description in any place other than the test room or the laboratory. The micro-indicator is an instrument that appears to offer a solution to some of the above difficulties, but unfortunately the diagram produced is so small that it can only be examined under a power microscope, and cannot be measured at all by a planimeter. It can, however, be magnified by optical projection when the diagram produced is very similar to that of the optical indicator. This additional process is a great disadvantage since the diagram, to be completed, must be treated in a separate apparatus. There is apparently only one point that can be raised against it apart from the smallness of the diagram, and that is, the effect or influence of the scriber friction upon the celluloid disc. This friction is evidently not very great but it cannot be overlooked, that whatever error does exist originally, will be very greatly magnified in the enlarging process.

The diagram that we are so familiar with, based on pressure and piston displacement, has prevailed since the days of Watt and to which engineers have become so accustomed that they rarely think of any alternative method. The ordinary pencil indicator is no doubt quite accurate for speeds up to 300 revs. per minute, but it must be borne in mind that when the speed is increased to 2,000 revs. per minute the difficulties caused by the effects of inertia have been magnified thirty-six times. The outstanding advantage of the pressure volume card, is that horsepower can be measured directly from it, but when this form of indicator is used with the internal combustion engine, the most important part of the stroke is crowded into the very portion of the card where the displacement is least. This difficulty, however, can be overcome by setting the paper half a stroke or 90° out of phase with the piston. The diagram under such conditions remains the same length but the part of the stroke that we wish to analyze is drawn out, whilst the less important part of the card, as far as this particular investigation is concerned, is compressed. This however, only applies to low-speed internal combustion engines, otherwise the error due to inertia will invade our diagram results.

An Important Test

Most engineers are familiar with the knowledge that overstrained steel or iron has the power to automatically recover its elastic properties if allowed to remain at rest for any length of time. This fact is very noticeable in rolling mills, wherein the physical properties of steel bars vary very materially, comparing those that have been rolled, and those that have stood for several days. This, however, does not give us any definite information upon the actual time it takes steel to recover from a very definite overstrain. Some very interesting tests have just been completed by the Research Department at Woolwich, which were commenced some thirty years ago by Sir Alex. Kennedy. These were commenced with a view to making a systematic test and obtaining reliable information upon the auto-recovery of structural materials. The work has been completed by R. H. Graves, B. Sc., in whose report some very interesting facts have been recorded.

Mr. Graves has shown that during the thirty years that have elapsed since commencing these experiments, the specimens of steel and iron have completely recovered their elasticity, except in the case of some very hard steel specimens which had only shown signs of slight recovery. The recovery of these bars, however, was rendered complete by subjecting them to a temperature of 175 deg. Cent. for a period of one hour. In the case of crucible steel, the recovery in thirty years was about as much as would be brought about by subjecting the specimen to a temperature of 100 deg. Cent. for one hour, and considerably less than if it had been kept for the same length of time at a temperature of 125 deg. Cent.

One very curious fact that was observed, was that wrought iron extended less for a given maximum load, beyond its elastic limit, when loaded slowly, than when the load was instantly applied. The explanation given is that the auto-recovery of iron is very great, and that this process goes on even when the specimen is under an overstraining load, provided the load is only applied gradually.

Our Question Box

Question.—There is a slight bulge in the crown sheet of the fire-box of a locomotive boiler that is under my charge. It occurred prior to the boiler being purchased by my firm, and was evidently caused due to the boiler at some time being short of water. The plate, although this must have overheated, was not burnt, and furthermore, the stay at this part, that was fractured, was renewed. The boiler appears to me to be safe but the point is, how far could such a defect go to and cause the boiler to be unsafe?—R. J. B., Forest.

Answer.—We are not informed the manner in which the crown sheet is stayed, which we must say is a factor that affects the situation very materially. If the crown sheet is supported by sling stays attached to the shell or barrel of the boiler, we could allow the defect to go much further than if the crown sheet was supported with girder-bars only. We will analyze both methods of staying so that we can actually see the effect a bulge would have in each case.

To understand the situation properly, it would be best to consider the fire box without any form of stays whatever and to note its behaviour under pressure so that we will know exactly how far it is self supporting. Let us imagine there is 20 lbs. of steam on the boiler and the crown sheet of the fire box begins to bulge at the centre. We could fit a stay at this part and attach it direct to the shell of the boiler in which case the shell is supporting the load. We could, on the other hand, fit a girder bar across the crown, the feet of which would be resting on the front plate and tube plate of the fire box. By staying the crown plate to this girder bar it will be seen that the load on the girder bar comes directly on the front plate and tube plate of the furnace. Suppose we increase the pressure in the boiler to 40 lbs., the crown sheet will again commence to bulge at a distance equi-distant between the centre stay that we have just fitted, and the edge of the plate. This bulge will in turn have to be supported by several additional stays placed in a circle around the first one fitted. If these stays are attached to the shell of the boiler, the load is supported by this plate, but if attached to the girder bar, the load is taken on the front plate and tube plate of the fire box.

It will, therefore, be seen that by using a girder bar, the total load of the fire box crown comes directly over the front and tube plates of the fire box. If these plates are perfectly straight, they can carry the load without trouble, but if they become slightly distorted or drawn in, due to the crown sheet bulging, the situation becomes dangerous.

It is therefore evident that the bulging of a fire box crown, from a structural standpoint, is not serious providing the plate is not damaged and the stay is not broken. If the boiler is fitted with girder bars and the bulging of the crown plate has been sufficient to drag or bend in the front or tube plate, then the situation immediately becomes serious, as these plates must be straight to withstand the load.

It must not be overlooked that in the above we are only speaking from a structural standpoint. A bag or bulge in a fire box crown is a receptacle for scale, mud or other impurities in the water, which, if allowed to deposit in the damaged portion of the plate, would be sure to cause further trouble. It is advisable in the case of a bulge in the crown sheet of a fire box, to have it set back as soon as it is conveniently possible.

Question.—What is the advantage of using zinc in a boiler in preference to soda, to arrest the corrosive pitting of a plate?—T. H. D.

Answer.—When zinc slabs are placed in a boiler to arrest corrosion, it is usually on account of some special reason, to prevent the water from being contaminated with chemicals. It may be possible that in the process of manufacture, it is imperative that the steam from the boiler should be unpolluted with the small particles of the treated water being carried over in suspension with the steam. In this case zinc slabs can be used to great advantage to arrest any galvanic action that is taking place in the boiler. They should be given a metallic contact, and firmly secured in a position where the corrosion is most active.

Question.—Is it just as economical to heat the feed water of a boiler by direct contact with exhaust steam, as it is to use a surface heater?

Answer.—It is perhaps a little more economical to heat water by the first method although it is not always advisable, on account of the possibility of there being oil in the exhaust steam passed over from the engine, which is liable to pollute the feed water and cause overheating of the boiler plate. It is a difficult matter to separate or intercept oil that has become emulsified with the water. It is, therefore, for this reason that the surface heater system is the best. An engineer will be well compensated for the small loss in heat units, by the greater efficiency and less trouble with his boilers, which is a factor that he must study before deciding upon any system of feed water heating that he intends to instal in his plant.

TITANIUM STEEL ALLOYS

The use of titanium as an alloying element for steel is shrouded in secrecy. According to information supplied to the United States Bureau of Mines, carbon-free ferro-titanium has been employed in Europe for making an electric steel containing 5 to 7 per cent. titanium. Rumors of the use of titanium-alloy steels for armor plate have been circulated, but so far as is known, no merit has been found in the addition of titanium to steel as an alloying element, and experiments with steels containing 0.1 to 1.0 per cent. titanium have shown no special advantages. A more interpretative investigation than any so far carried out, is required to distinguish clearly the merits of titanium-alloy steels, and it must be assumed now, pending exact proof to the contrary, that these steels are of no particular value, or at least yield no advantages not provided by other steels. It is rather difficult to get the carbon-free ferro-titanium to alloy with steel without much loss of titanium, and this fact, coupled with the high price of carbon-free alloy has tended to discourage experimentation by steel makers in this direction. It is possible, however, that if the cost were less, some combination of titanium, either alone or with other metals, might produce valuable steels for some purposes. Titanium increases the hardness of steel, and experiments on titanium steels have been made by Guillet, Braun, and Lamort. It has been shown recently in Bulletin 199 of the Bureau of Mines that fair recoveries may be expected with carbon-free ferro-titanium, provided the alloy is added at the end of the heat, and the steel is very hot.

Tenders are being asked on the first unit of a power plant to be erected at Powell River, B. C., for the Powell River Company, Ltd., Vancouver. Tenders will be received by N. R. Lang, manager, for a power house and a smoke stack.

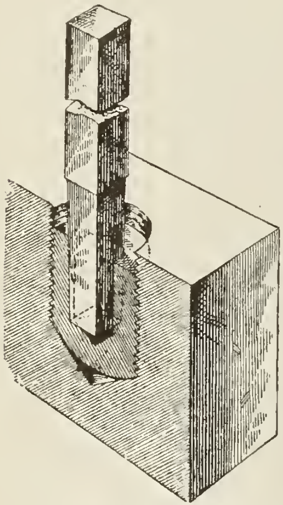
Operators' Point of View

REMOVING BROKEN STUDS

By E. Lytton Brooks

The accompanying sketch shows a quick and simple method or removing broken studs or setscrews having either right or left hand threads. It is more efficacious and workmanlike than the three-cornered file stunt; the file having a nasty habit of splintering up or breaking off in the hole.

A piece of square tool steel (conditions governing the length and size) is chosen and the square ground to a gradual taper toward one end. A hole is then drilled in the stud which will not quite admit the tapered end of the square steel. The square piece is then driven in tight and the stud can be unscrewed by the application of a wrench.



REMOVING BROKEN STUDS

A WORD ABOUT SMALL vs. LARGE ENGINES

By N. G. Near

We have all heard people express astonishment at the immense power developed by small engines, such as the automobile and aeroplane engines. They are the most powerful of all prime movers per pound weight. The average engineer therefore ponders in his mind the question, "Why won't an engine ten times as big as an aeroplane engine, develop ten times as much power? by 'ten times as big' he means, 'with piston area ten times as large'."

This brings us back, in a way to the old paradox of models—if it can be called a paradox. It has long been known, for instance, that a model of a bridge 1 100 as long as the bridge itself and with all other dimensions correspondingly reduced, will hold a much greater load in proportion to its size than will the large bridge. The ratio of this increase in strength is also well known. A small model of a water tank, would be far too strong for water. It could hold mercury, if necessary. For water the thickness of shell and size of struts can be much reduced in the model, and it will still hold its proportionate volume of water.

A small engine, if run at the same speed as large engines, however, would not develop its rated or computed power because the smaller engine has a larger proportion of friction to overcome. The mechanical efficiency of small engines is generally low and the reason therefor is easily explained: For example, the circumference of a 10 inch cylinder is 31.4 inches, while that of 1 inch cylinder is 3.14 inches. The piston areas are 78.54 sq. inches and .78 sq. in. respectively. Therefore, where the drop in areas is 100 to 1 the drop in circumferences is only 10 to 1. Now since friction in a cylinder, piston rod, valve rod, valve, etc., is dependent on the "friction surface" and not on the areas of the piston and rods the mechanical efficiency must be considerably less for the smaller engine.

Besides, large engines cannot be operated at the speed of the small engine. The large reciprocating parts are too heavy. There is too much inertia to be overcome. The energy in reciprocating masses is always equal to

$$\frac{W\ V^2}{2g},$$

where W is the weight of the reciprocating part, V is the velocity of the part in feet per second, and g=32.16. It is clear that enormous forces would be necessary to constrain such energy, for the ponderous reciprocating masses would have to be stopped and started several thousand times per minute where the engine must run at 2,000 r. p. as is common in small gasoline motors. The connecting rod would have to be correspondingly long, and it is on this rod that most of the stress would fall. At the "out" end of the stroke it would be subjected to a severe tensional force. At the "in" end the force would be compressive with the same vengeance. And at the same time the connecting rod would tend to bend or "whip" due to its own mass and high speed in lateral directions. A big connecting rod is much weaker in proportion to its size than is a small one. Hence, in many more ways than one it is almost a physical impossibility to make a large engine operate at the speed of a small one.

The large engine is valuable mainly because it is most economical. It consumes less energy in friction, as I have already pointed out; steam and gases are not in a "hurry" in and out and thus expend energy in "bombardment," expansion of the gases is more complete; there is less back pressure; and the large engine is usually longest lived. There is less wear and tear.

For these reasons then the two types find their respective places. Although inefficient and short lived, the light engine is used in aeroplanes and automobiles, and although expensive as to first cost and a great consumer of space the large engine is used in the stationary power plant.

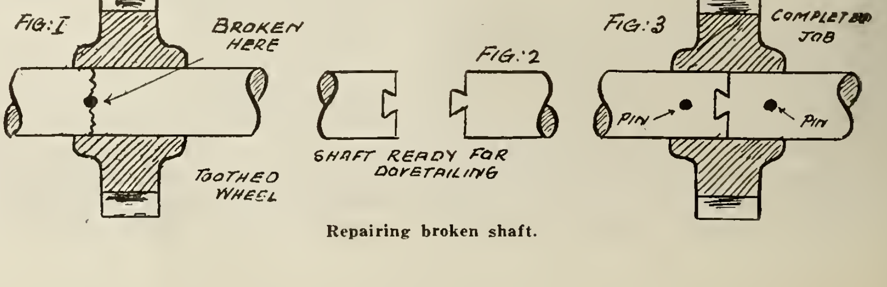
A BROKEN SHAFT

A shaft which had a small gear wheel pinned on to it, broke right across the pin-hole, putting it out of action, at a time when I could least spare it. Seeking to save time and expense I employed the following method of repairing it.

I removed the gear-wheel and filed the broken ends of the shaft true.

I then cut a slot, with two hack-saw blades, about a ¼ of an inch deep in one of the trued up ends of the broken halves, and filed a projection in the other half

(Continued on page 36)



Repairing broken shaft.

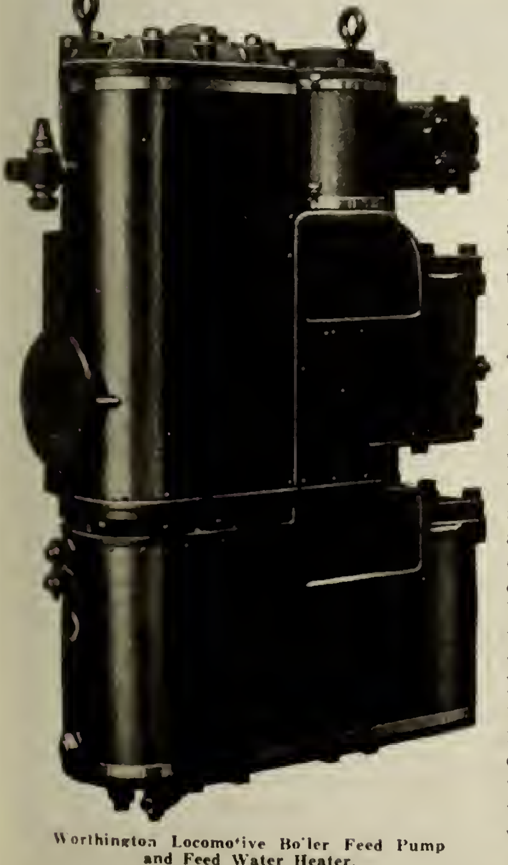
Progress in New Equipment

THE WORTHINGTON HEATER AND PUMP

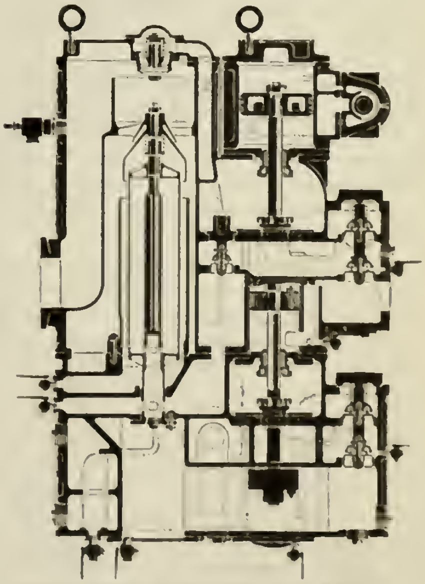
The general construction of the heater and pump is shown in sectional view. The heater is a simple cast iron box, to one side of which the pump is attached. The large opening in the side of the heater is connected by a pipe to the exhaust ports of the locomotive through holes cut into these ports through the back of the cylinder saddle. The open space in the top of the heater is, therefore, supplied with exhaust steam from the locomotive at practically exhaust port pressure. This pipe leading the exhaust steam to the feed water heater has in it a check valve and an oil separator. A small hole in the bottom of the oil separator provides a continuous drip for the oil which is separated from the exhaust steam, effectually preventing this oil from entering the heater and reaching the boiler.

The feed pump is of the vertical, direct-acting piston type, with the steam cylinder above and two water cylinders below. The upper or cold water cylinder takes cold water from the tender through the usual hose and pipe and delivers it to a spray valve in the top of the heater which sprays the water into the exhaust steam filling this part of the heater. This cold water condenses as much of the exhaust steam as is necessary to heat it and, mixing with the water resulting from the condensation of this exhaust steam, drops to the bottom of the heater. The lower pump cylinder takes this heated water from the heater and delivers it to the boiler.

The bucket is shown in the sectional view of the heater on this page. When there is too much water in the heater the bucket fills and sinks. In its low position the bucket opens ports in the central stem, allowing the excess water to reach an extra suction valve in the cold water cylinder. The water thus returned to the cold water pump meets a correspondingly reduced amount of water coming from the supply through the main suction valve and is delivered with it to the heater through the spray valve. After the excess of water has been pumped from the heater and the bucket is partly emptied, the bucket rises, closing the return passage so that the return valve is then out of commission and all of the water is taken from the tender through the main valve.



Worthington Locomotive Boiler Feed Pump and Feed Water Heater.



Section through Feed Pump and Heater.

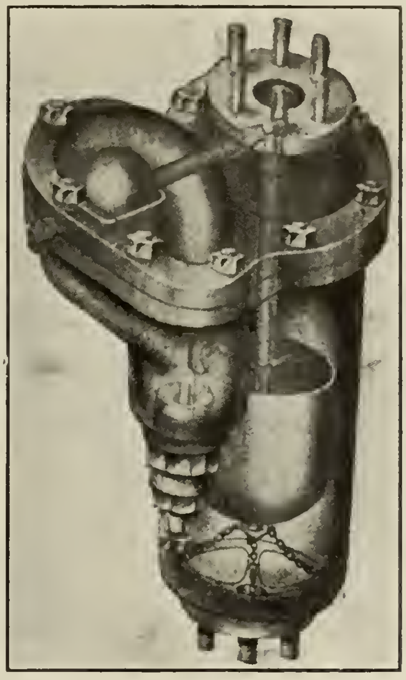
TODD GUARDIAN

The Todd guardian is an invention resulting from the increasing use of oil as fuel, being designed to automatically shut off the oil supply to the burners, when through any unforeseen condition the water has become dangerously low in the boiler.

The action depends on the water level in the boiler, which causes a bucket to fall. This movement sets a cradle in motion, permitting steam to escape to an oil supply stop valve.

The device consists of a cast-iron body having two chambers. In one is a bucket float with anchor and chain suspensions to prevent the bucket from touching the sides of the chamber. The float is connected to a spindle. The steam connection is at the top and the water at the bottom. The bucket is always full of water, and it balances when four-fifths of its height is immersed in water.

When the water level falls in the boiler, it also drops in the float chamber, and the weight of water in the bucket will, at the danger level, produce by its weight a strong downward pull on the spindle and cause the cradle to tip, whereupon a ball falls out and strikes the ram head on top of a cartridge. The ram has a peculiar shaped point which perforates a copper disc and allows steam to escape through the opening thus made. The steam enters a stop valve above the diaphragm, which auto-



Todd Guardian.

matically shuts off oil fuel supply to burners.

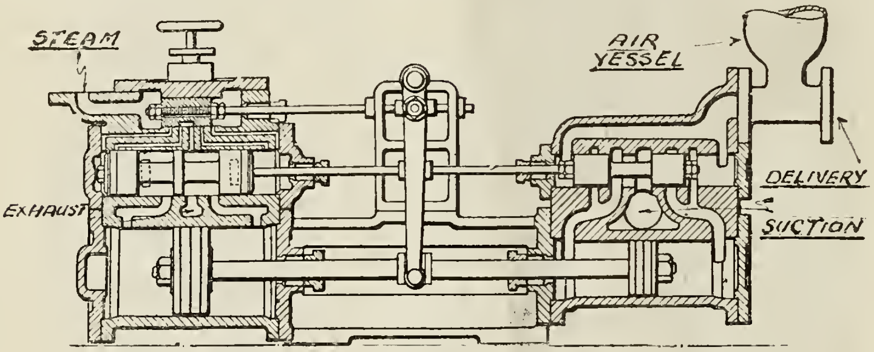
As the cartridge is a complete unit, it is easily inserted, but not until the ball has been pushed back into the cradle by means of a rod.

The above economy and safety devices must appeal to the modern engineer, who on account of his special training demands a high factor of safety together with efficient and economical operation.—The White Fuel Oil Engineering Corp., 742 East Twelfth St., New York City.

VISCOS FUEL PUMP

The accompanying diagrammatic illustration shows a special design of pump made by the Moorlands Engineering Co., Ltd., Leek, Staffs., and 37, Moorfields, Liverpool, for dealing with oil fuel, molasses, and all liquids of high viscosity.

The pump, as illustrated, is of the direct acting type, having a steam piston and pump piston connected to the same piston rod. The steam to and from the steam cylinder is controlled by a steam operated piston valve. The steam to and from the steam operated valve is controlled by a mechanically operated slide valve in the steam chest. The slide valve is operated by means of gearing from the crosshead on the piston rod.



Pump for heavy oils.

Whereas, in the ordinary types of pumps the passages to the pump cylinder are controlled by some form of lift valve or disc, mitre, or ball type, in the Viscos pump these passages are controlled by a piston valve which is connected directly to the steam operated valve controlling the passages in the steam cylinder. By this unique arrangement the pump valve is positively operated, no matter how viscous the liquid being dealt with.

A very important feature of this arrangement is that the suction or inlet passage to the pump cylinder is full open at the very commencement of the stroke of the pump piston, due to the fact that the pump valve which controls the passages in the pump cylinder being connected to the steam operated valve, shoots over instantaneously immediately the pump piston reaches the end of its stroke. The only correct arrangement is to have the inlet passages full open at the very commencement of the stroke, as the acceleration of the piston is greatest at the commencement. In pumps fitted with lift valves the suction valves are shut at the commencement of the stroke of the piston, as the valves rely for their action upon the difference in pressure created by movement of the piston. This defect becomes very pronounced when liquids such as heavy fuel oils at low temperatures have to be dealt with, so much so that the pumps refuse to function.

The type of pump illustrated, deals positively with heavy fuel oils at 32 deg. F., cold colloidal fuel consisting of 50 per cent. Mex. fuel oil and 50 per cent. coal dust, petroleum jelly, and all liquids of high or low viscosity.

A regulating valve is fitted in the steam cylinder, which ensures the steam operated valve being supplied with steam at the full available boiler pressure, regardless of the working pressure in the steam cylinder.

Another unique feature is that the Viscos pump will work equally as well horizontally as vertically without change of design.

Although the illustration only shows the single cylinder type, Viscos pumps are also supplied in the duplex type, for dealing with the fuel oil, etc., in large quantities. The pumps are made suitable for any capacity, and to work against any pressure.

WEIGHING ATTACHED IRREGULAR PARTS

W. F. Schaphorst

Occasionally it is desired to know the weight of some part or other on a machine, but the part cannot be detached easily for weighing and it is too irregular to compute with ease. In such case the weight can be found indirectly by weighing the water displaced by the part, if the part projects in such a way that it can be made to displace water.

For example the writer once had to determine the weight of a flywheel governor weight, which was made of cast iron, and which could not be detached without removing the whole governor from the engine.

I turned the flywheel to such a position that the weight was at its extreme low point. I then procured a rectangular sheet metal vessel and filled it with water. I weighed the vessel when it contained as much water as could be held in it.

Then I carried the vessel of water over to the engine and raised it so as to envelope the weighted end. Water was displaced, of course, but that is what was wanted. I raised the vessel until the water level cut the governor arm, being sure all the while that the vessel was still holding as much water as possible while raised to that height.

Then I removed the vessel and again weighed it, this time with the remaining water. The weight of the governor end was then computed in this manner:

The first weight was 45.5 pounds and the second weight was 39.25 pounds. The weight of the water displaced was therefore

45.5 — 39.25 = 6.25 pounds.

Now to compute the weight of the cast iron that displaced the water all that is necessary is to multiply by the specific gravity of cast iron, which is 7.207 or 6.25 × 7.207 = 45 pounds.

The remainder of the arm was of rectangular cross-section, whose weight was very easy to compute on the basis of 0.26 pounds per cubic inch, which is the weight of cast iron.

In case other metal parts are to be weighed in this manner, here are the specific gravities of metals most commonly used in mechanical constructions:

Cast iron	7.207
Wrought iron	7.78
Soft steel	7.833
Steel castings	7.917
Cast aluminum	2.60

Should it be desired to know the volume of the piece of metal in cubic inches, divide the difference in weight (which is equal to the weight of the displaced water) by .0362. The result is the volume of the part in cubic inches.

This latter test will come in handy for finding the volume of any irregular substance that can be submerged in water without harm or without any absorption of water. Or, should one wish to find the specific gravity of coal, brick, rock, etc., this method, reversed, will serve the purpose. Weigh the rock, say, and then weigh the displaced water (which can be done by subtraction as already explained). Divide the former by the latter and the quotient is the specific gravity of the rock or other substance.

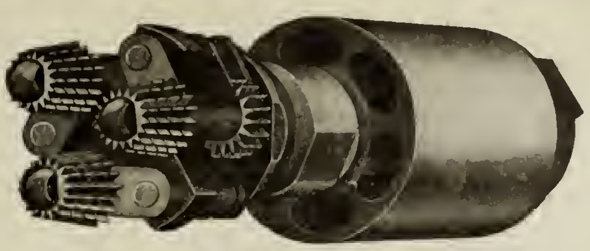
A BROKEN SHAFT

(Continued from page 34)

to fit in the slot and dovetailed the two together making them a snug fit. (See Fig. 2.)

The gear-wheel, which had only one pin-hole, I then replaced on shaft, carrying the existing pin-hole through the shaft, so as to clear the dove-tail joint. On the other side of the boss of the gear-wheel I drilled a corresponding pin-hole.

I then drove in a couple of steel taper pins, cutting off the ends level with the boss of the wheel, which served the double purpose of holding the gear-wheel and strengthening the dove-tail joint at the same time (See Fig. 3). The shaft was put into service and has run quite satisfactorily since.—H. Godfrey.



Standard Water Driven Tube Cleaner

KEEP YOUR BOILERS CLEAN

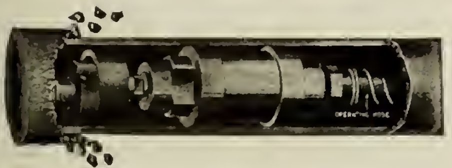
All natural waters contain some impurities which, when introduced into a boiler, may appear as solids deposited on the heating surface. No matter what the substance consists of, it must be removed at frequent intervals or it will decrease the capacity and efficiency of the boiler and may cause it to be badly damaged by over-heating.

Some waters, notably well waters, deposit such quantities of scale that they should be purified before going into the boiler, thereby preventing an accumulation of incrustation and consequent damage to boiler parts, and at the same time effecting a large saving in fuel by keeping all parts of the heating surface in a clean and efficient condition. If you have bad feed water it is a case for the chemist, for the scale is probably composed of several substances which must be known before the exact treatments necessary to get rid of them can be determined upon. The use of treatment without technical advice is poor policy.

Stony and vegetable matter in suspension can be removed by FILTERS, which we supply in various sizes and designs to suit all requirements. In most Canadian plants, lake or river water is used for feed, and these waters seldom carry large quantities of scale-forming materials in solution. Scale can be allowed to form in boiler for a considerable period. Experience in each individual plant determines the limit at which tube difficulties will begin or a perceptible falling off in efficiency will take place. With such a limit of scale formation fixed, and the danger of allowing it to be exceeded, well understood, probably the most economical and efficient method of keeping the heating surfaces clean is by use of the LAGONDA TUBE CLEANERS.

Lagonda Water Driven Cleaner for Curved Tubes

Lagonda Air Driven Cleaner for Straight Water Tubes



Cleaner Removing Scale from Outside of Fire Tube

The cleaners are designed and so constructed as to thoroughly remove all the scale, in the shortest possible time, at the lowest cost of operation, and they require a minimum amount of repairs, reducing both the waste boiler time and labor cost of cleaning.

They are made to operate by either water, air or steam. In every case a swing head is furnished so designed that three sets of cutters are thrown out by centrifugal force against the scale in such a manner that they make straight line contact with the tube and they do the work without damage to it.

You can be supplied with LAGONDA tools for cleaning Economizers, Condensers, Evaporators and other tubular plant.

We shall be very glad to furnish full particulars

TORONTO OFFICE, BANK OF HAMILTON BUILDING

The Welding of Cast Iron

IN the course of a discussion on the subject held by the American Welding Society it was poited out that cast iron differs widely in composition and characteristics. It always contains about 3 per cent. of carbon, but this may be in a combined graphite state, and it may hold widely varying amounts of other elements, such as silicon, manganese, sulphur, and phosphorus. Not only the presence of these elements, but also the rate of cooling of the casting, profoundly affect the physical characteristics and weldability of the metal.

In making a weld in commercial cast iron, the surfaces which are to be joined must again be melted. These surfaces consist of iron which contains carbon in both the free and combined states. When these surfaces are melted, several things happen. First, both the graphitic and combined carbon go into solution in the molten metal. Second, some of the carbon, silicon, and manganese is burned out by the heat, while the amounts of sulphur and phosphorus are practically unchanged. Silicon is most easily burned out, so the tendency is to produce cast iron in the weld that will be white when cold, owing to its low silicon and carbon content. Third, the surface of the molten metal oxidises, making a slag, which in a measure prevents further oxidation. As soon as the welding heat is removed, the melted iron solidifies very quickly, owing to its proximity to the comparatively cold mass from which it has been melted and to its being exposed freely to the air. This sudden cooling causes a large amount of carbon to be retained in the combined state, resulting in a white, hard metal in the weld. Of course, if the casting has been preheated before welding the cooling of the added metal will not be so sudden, and a softer machinable weld may be secured. Experience has shown that the grade of cast iron which is most difficult to weld successfully is that which is soft and has an open grain. However, little difficulty is encountered when the metal is of comparatively thin section (½ in. or less.)

When iron is molten, or even red hot, it oxidises very readily if exposed to air. In welding, the surface of the molten metal becomes covered with iron oxide, which may be deposited in the weld by mixing with the molten metal, or by being tapped between two layers of metal at different times. In either case the result will be a weak, non-homogeneous weld, for the oxide particles segregate and do not form a junction with the adjacent metal.

The shape of the castings also has an influence on the method of welding to be used. A casting comprising both light and heavy parts is subjected to more external stresses than one of homogeneous cross-sections. The stresses are caused by the different rates of cooling, light sections cooling more rapidly than heavy. There are also internal stresses set up at sharp angles.

When in the welding of cast iron a filler metal of different composition than that of the casting is used, serious consideration must be given to the fact that the co-efficient of expansion, and consequently the shrinkage of the metal in the weld, may be different from that of the rest of the casting. The different shrinkages of the two metals will cause one to slide on the other as they pass from the liquid to the solid state. The shrinkage sets up internal strains which the ductility of the welding materials must take care of. Altering the carbon content from the combined to the graphitic state helps to increase the shrinkage. If the iron contains a weakening agent, the internal strains set up by shrinkage often cause cracks to appear.

Utilization of Waste Fuels

IN VIEW of the decreasing supply and the increasing cost of high grade fuels, the efficient utilisation of fuels of low grade, including what are known as "waste fuels," is becoming a problem of major importance to many industries and to commercial progress. Important sources of "waste fuel" include sawdust, shavings, scraps, edgings, tanbark, wood extract chips, paper mill refuse, bagasse or spent sugar cane, and city refuse.

Perhaps one of the most important waste fuels has been spent tanbark. A rough estimate would indicate that in the United States this material generated a few years ago an amount of steam that would have otherwise required the yearly consumption of about 2,000,000 tons of high grade coal. Yet at one time this valuable fuel was considered a mere detriment and an expense to the leather industry. It was disposed of by dumping it into rivers, by filling in waste ground, and by making roads with it, often necessitating the payment of large sums for its disposition. The improvement of a furnace converted a substance supposedly incombustible into a valuable waste fuel and an enormous waste was converted into an equally great saving.

Sawdust and wood waste are of course largely available in many districts. With sawdust the saw mills produce waste wood in the form of edgings, end cuts, shavings, and various forms of blocks and scraps. At many plants in lumbering districts the bulk of this material is so great that it not only supplies power and heat for the mill but furnishes electric lighting for towns, and even then in order to prevent its accumulation a large destructor is kept constantly in operation as well and the heat from the burning wood is wasted to the atmosphere. If there were a market for electric power within a reasonable distance, this waste could be converted readily into an economy. Even now plans are being considered to prevent such waste, and at least one plant is in operation for producing wood alcohol and other chemicals from such material. Plans have for long been considered intended to make possible its use also for wood pulp in the paper industry. Sawdust and wood waste are of course readily convertible into gas that may be used as fuel in gas engines.

Bagasse is the by-product fuel resulting from the manufacture of cane sugar. The juice from the cane is extracted by crushing and the remaining fibrous material, known as bagasse, is conveyed to the boiler house, where it is fired in special furnaces and is made to produce all or part of the steam required to operate the plant. The fuel is in the form of strips 3 to 8 in. long, but much longer pieces may sometimes come through the mills. There is said to be much room for improvement in the design and in the control of furnaces in many plants burning bagasse; these two factors often make the difference between running the boiler plant on very little or no purchased fuel and of spending large sums annually for coal, oil or wood.

Coke breeze is another by-product fuel which can be effectively used under proper conditions, while city refuse belongs to the class of fuels that, by proper application of the principles of combustion, have been promoted from semi-combustible to auto-combustible fuel. Though this heterogeneous material can be disposed of by dumping at sea or on waste land—sometimes in an inexpensive manner—the consensus of opinion is strongly in favor of its disposition by burning. The strength of this opinion is largely due to comparatively recent improvements made in the design and efficiency of destructors or refuse burners. Furthermore, when combustion is complete, burning is by far the most sanitary method of disposing of offensive materials. Some of the collected matter, chiefly the house garbage, contains so much moisture in comparison with its low heating value that to burn it alone is impossible, but by mixing this with all the other refuse, the calorific value of the mass is made high enough not only to evaporate its contained moisture but to produce effective evaporation in a boiler as well. Even when this is done, however, it is necessary to depend for efficiency on correct design and careful operation of the furnace.

Results of a special study of the economic combustion of waste fuels have recently been published in Technical Paper 279, compiled by Mr. D. M. Myers, and can be obtained from the Bureau of Mines, Washington, D. C.

The Conveyors Corp. of America, 326 West Madison St., Chicago, Ill., has issued a new folder describing the American air tight door. This door is largely used in ash pits and boiler settings and is made in five sizes: 15 x 16, 18 x 18, 22 x 26, 24 x 24 and 24 x 36. The door is of unique design, strong and substantially built of cast iron. When closed and locked it is air tight. Copies of the new folder will be sent to interested readers.

The modern fire box demands binding cements of higher fusion resistance with the physical strength and elasticity to give and take under temperature stresses in the brickwork.

Don't blame your fire-brick

—they last longer if you lay them up properly

APPEARANCES make it easy to blame good fire-brick for premature furnace lining failures—for even the best brick fails if it is left in the lurch by its binding cements.

Ordinary fire-clays and cements fuse or are crushed from the brick work by the great temperature stresses set up by present-day firing. The sides of the brick become exposed to the flame. The brick "heat soaks" and fuses or spalls away.

Careful research shows that the life of fire-box walls can be economically prolonged by the use of better cements, which give their fire-brick proper support. A complete line of such cements has been developed by Johns-Manville together with a method of application known as Johns-Manville Heat Treatment.

The use of Johns-Manville High Temperature Cements and Heat Treatment brings a direct saving in lower maintenance cost and an important indirect saving through less frequent boiler shutdowns.

ENGINEERS' COUNCIL

Hamilton council, No. 60, of the Universal Craftsmen Council of Engineers, is fast becoming a live organization. Membership is increasing rapidly and the executives are energetically promoting its social and educational features.

Those who were present at the regular meeting were fortunate indeed in the opportunity afforded to enjoy the illustrated lecture by C. A. Price, of the Canadian Westinghouse company, on The Maintenance of Electrical equipment from a Manufacturer's Standpoint.

Refreshments were served and an hour of sociability and mutual discussion ensued around the festive board.

Past Worthy Chief W. A. Sweet supplemented a few remarks on the subject in moving a vote of appreciation as did Worthy Chief Alex. Leckie in extending the same to the speaker.

A vote of thanks was also extended to Bro. Gill, who provided the lantern.

At the next regular meeting in March, Brother G. Lindgrin, of the Steel Company of Canada, will speak, giving an insight into the steel and iron industry.

A SAFETY BELT MOUNTER

One of the commonest things to occur in a workshop is for a belt to slip off a pulley. The operation of replacing the belt requires a certain amount of skill, particularly to avoid accident. If the pulley happens to be placed rather high there is quite a serious amount of risk in getting the belt back again, to say nothing of the time lost in fixing ladders and other means of reaching the pulley. All these troubles and dangers are now a thing of the past, thanks to the invention of a safety belt mounter by a British engineer. This device consists of a flexible jointed arm fixed on a rod and carrying at the top a horizontal arm on which is mounted a small wheel. This arm is slipped under the loose belt (which is prevented from slipping off by the wheel) and a special spring arrangement inside the flexible arm enables the user to stiffen the arm sufficiently to pull the belt over the pulley. The arm is then carried round by the pulley until it reaches the point where the belt leaves the pulley and is thus released. With this ingenious appliance the operation of belt replacing is carried out in a few seconds without the slightest difficulty.

Conveyors Corporation of America, manufacturers of coal and ash handling equipment, Chicago, announce that they have acquired all rights to the Green steam jet ash conveyor, formerly owned and controlled by the Green Engineering Co., East Chicago.

SELLS AMERICAN RIGHTS

Major Forbes Keith, who recently succeeded in inventing and patenting a small domestic motorless refrigerator that works on the absorption principle and is operated by electricity, has sold his American rights to the Delco Light Products Co. of Dayton, Ohio, for an amount involving millions of dollars. The Canadian rights for making these refrigerators he retains himself.

A contract has been awarded by the Toronto Transportation Commission for four 6 x 20 feet horizontal return tubular boiler, 125 lb. working pressure, built to Ontario codes, to the Engineering and Machine Works of Canada, St. Catharines. A large breeching construction, 7 feet by 5 feet, and 60 feet long, connects the boilers to the stack. These boilers will be installed in the new $1,000,000 repair shops being erected on Bathurst St., by the T. T. C.

OBITUARY

C. W. ANDREWS.

C. W. Andrews, well known as an operating engineer, who for the last 13 years has been associated with the Boiler Repair & Grate Bar Co. of 86 Church St., Toronto, died recently and is survived by two sons and one daughter. He was in his 67th year when he died and was well known throughout the country. Many engineers will remember him as the compiler of the "Engineer's Lamp." He had been an operating engineer previous to his connection with the above concern.

Three Underfeed Stokers, multiple retort, A. C. type, are being installed in Chateau Lake Louise, Alberta. This is the 6th C. P. R. hotel to instal this equipment.

C. A. S. E.

On February 20, 1923, The Toronto No. 1 C. A. S. E. held an educational meeting which was very largely attended. The subject for the evening was—"Makers and Types of Engines." A number of papers were prepared and presented by members of the Association and the one which was prepared by Mr. R. McLaren, chief engineer of Massey Harris Co. was the one selected for discussion. The engineers in attendance evidenced quite an interest in the various types of turbines and the description of the Uniflow engine, with its modifications.

Several new members were introduced, and from the number of applications on hand it would appear that the membership was going to increase as a result of the educational campaign which has been carried on so consistently all throughout the season.

The question of the Board of Examiners of the Province of Ontario issuing special licenses for plants which are only operated temporarily either in the nature of canning factories, creameries, etc., was taken up and discussed very thoroughly and the consensus of the opinion of the meeting was that the Board should be given power at its discretion to issue such temporary licenses; however, it was considered best that certain safeguards should be introduced along with such a bill as the provision that such special licenses were not to be issued in buildings employing more than seven people and in no case in densely populated districts.

A large number of members were reported sick; however, the members were pleased to see that the patron of the organization "Daddy" Turner was on hand with his usual smile. Mr. C. B. Turner, better known as "Daddy" Turner, has been appointed chairman of the Exhibitors Committee in connection with the coming convention to be held at the Toronto Technical School on June 25-26-27-28.

NEW PUBLICATION

Mechanical World Electrical Pocket Book, 4 in. x 6 in., cloth bound, 390 pages, price 1/6, published by Emmott & Co. Ltd., "Mechanical World" office, 65 King St., Manchester. Among the new features of this issue is a newly-written section on Electrical Measuring Instruments and Power and Alternate Current Circuits. The new additions to various sections are notes on Mercury Rectifiers, Lead Hydrate Cells, Cyc-Arc Welding and one on Transformers. There are many other minor additions that have been made in various permanent sections that has brought this book thoroughly up to date.

Meaford industries are busy, and with one exception all are running 10 hours per day. Seaman-Kent Company's plant is now working to capacity.

"SAFETY" Plastic Metallic Packing

For steam, water, air, gas, etc., is practically indestructible and may be used over and over again. It is

Packing in Cotton Tubes.

GUARANTEED TO LAST THREE YEARS WITHOUT RENEWAL

Packing in Bulk.

It is made of an alloy of the finest anti-friction metals, just hard enough for long service but not hard enough to damage any rod.

The metal is combined with the best lubricating material, making it practically SELF-LUBRICATING AND FRICTIONLESS.

Send for full particulars also about our "Safety" Superheat Sheet Packing.

How Much Coal Are You Wasting?

Blindfolding yourself to the fact that your boiler room is different, because you can see no pipe line leaks, or the water alarms don't blow very often—doesn't help to pay for the needless fuel waste caused by the invisible losses within the boiler furnaces.

Get at the REAL FACTS and at the same time give your men a positive and simple guide that will enable them to keep the plant at top notch efficiency—by installing the

BAILEY BOILER PANEL

The Bailey Boiler Panel is a combination of the Bailey Multi-Pointer Gage and Bailey Boiler Meter.

It shows, almost immediately, the effect of improper furnace adjustment and enables the men to make the necessary correction before a large amount of preventable fuel waste has taken place. Good work on the part of the men is shown up by the charts as well as any inattention. The engineer can check the efficiency of his men as well as that of the individual boiler.

Let us send you fully descriptive Bulletins.

Now *any* plant can have multiple retort stoking—

Trade-Mark

Advantages

Coal is underfed throughout—not overfed on to side grates. This is the only truly *underfed* side-cleaning stoker.

One simple moving unit for five or more retorts—The feeding mechanism of the *"lateral retorts"* is controlled independently of main feed, permitting ideal fuel distribution under all conditions.

Simplest cleaning mechanism—a perfectly balanced dump plate easily operated by hand.

No need for basement ash pits—A trench 6 to 18 inches below the floor line is sufficient excavation for ash pits. This greatly reduces installation cost and makes the stoker adaptable to boilers already in service.

Plate tuyeres—reduce siftings and lower replacement cost.

High air cooled front and rear tuyere blocks—keep fire and clinkers away from front wall and bridge wall, reducing furnace maintenance.

THE superiority of multiple retort stoking is generally conceded. There is only one factor that has kept certain plants from adopting it—its greater first cost.

Such plants were formerly compelled to accept a stoker of inferior range—but this is no longer necessary.

The *"Lateral-Retort"* Stoker combines the simplicity and the lower first cost and installation cost of a simple side-cleaning stoker with the high capacity and excellent combustion efficiency of the more complicated and higher priced multiple retort type.

The top view of the *"Lateral-Retort"* Stoker, below, shows how this is accomplished—the many advantages are listed opposite, and are covered in greater detail in the *"Lateral-Retort"* Catalog—*Ask for it.*

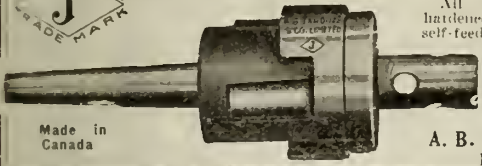
Jardine's Self-feeding Tube Expanders

REGISTERED J TRADE MARK



All have properly case-hardened bodies and are self-feeding and self-releasing. By reversing position of mandrel it is withdrawn without danger of breaking mandrel or straining expander.

Made in Canada

A. B. Jardine & Co. Ltd.
Hespeler, Ont.

"A De Laval Oil Purifier

makes a decided improvement in the running of the engine," says Chief Engineer Jenkins of the London Guarantee & Accident Co. in his report on the Diesels in the Chester Water Works, Chester, England. Mr. C. W. Bennett, the engineer in charge of the water works, writes: "About 3,000 gallons of lubricating oil have so far been treated and lubricating oil now costs one-third of the amount before the Purifier was installed."

Write for bulletin No. 105, which gives detailed information about De Laval Oil Purifiers.

HEPBURN PUMPS

Centrifugal and Reciprocating

The Selection of a Pump

—be it large or small, certainly involves an important responsibility, for few buyers can afford the expense and trouble which usually follows the installation of unsuitable or low-grade equipment.

All we ask is that your judgment be based solely on the performance of our pumps and your verdict given only after the capabilities of Hepburn Pumps have been proven conclusively.

We can also quote attractive prices on Hand and Electric Overhead Cranes, all kinds of Castings and Special Machinery.

Make Canada Prosperous by Buying Canadian Products

If The Pressure Becomes Excessive

Untold damage may result if fixtures are not protected. Preventative insurance by the use of a Mueller Relief Valve can be had at slight cost. Built to give service and satisfaction, each valve adapted for its particular installation it will fulfill the requirements in every instance.

It is dependable under all circumstances, does not stick even after long periods of inactivity and responds instantly when service is demanded.

Highly sensitive, positive in action, easily adjusted—it provides the Factor of Safety for all steam, air, oil or water lines.

More than 400 YARWAY BLOW-OFF VALVES used by Cleveland Electric Illuminating Company

Ten years ago, Cleveland Electric Illuminating Company ordered their first YARWAY BLOW-OFF VALVES—twelve YARWAY SEATLESS. Thirty-three times since then they have sent in repeat orders. They now have in service more than 400 YARWAY SEATLESS and YARWAY DOUBLE-TIGHTENING BLOW-OFF VALVES.

One of their recent orders was for 93 YARWAY SEATLESS to be used on economizers—a service fully as severe as boiler blow-downs, requiring a thoroughly good valve. Repeat orders come only when worth has been proved. A large proportion of YARWAY BLOW-OFF VALVES are sold to present users. The YARWAY SEATLESS BLOW-OFF VALVE and the YARWAY DOUBLE-TIGHTENING VALVE are fully described in an interesting booklet. To get your copy, ask for Bulletin B-410.

YARNALL-WARING COMPANY

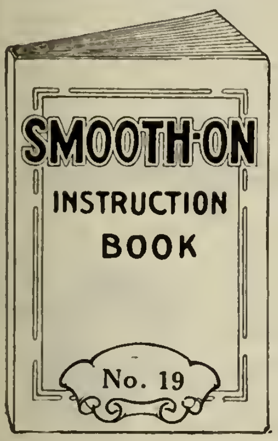
SMOOTH-ON IRON CEMENTS

What Other Engineers Know About Repair Work, This FREE Book Tells You

It is full from cover to cover of practical ideas developed to meet actual engine and boiler room emergencies. There is no theory in

SMOOTH-ON

Instruction Book No. 19



Just 144 pages of real engineering facts—facts that if you knew them might save you hours—or days—and dollars in your next repair job.

Write for your copy of this valuable book—you need it in your work—it's FREE.

Smooth-On Cements are sold in 5-lb., 10-lb., and 25-lb. tins; also in larger sizes.

A COMPLETE SERVICE IN

"John Crane"

FLEXIBLE METALLIC PACKING

PACKING THAT LASTS

John Crane packing of spirally wound babbitt foil impregnated with graphite wear as only a non-corrosive, non-abrasive metal can. Its simplicity is its strength—flexible, compressible, easily applied using the piston rings principle of the fluid seal. John Crane packings give length and quality of service previously unequalled in packing. Send for our text book "Metallic Packings."

When the Leviathan Goes to Sea

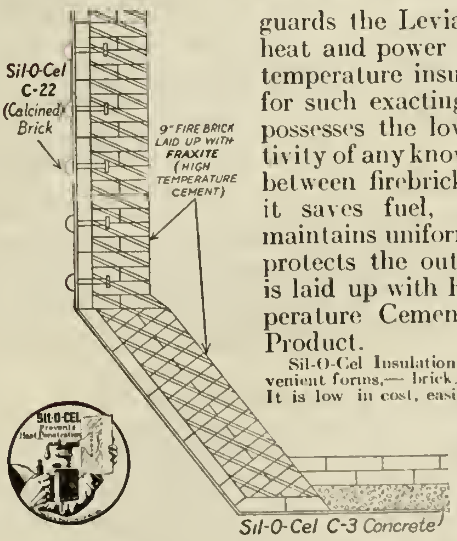
the pride of the U.S. Merchant Marine will represent the best efforts of American science and engineering. Deep within the heart of this magnificent liner, the steady pulse and throb of motive equipment denotes power,—power generated without loss or waste,—power conserved and utilized to the utmost.

SIL-O-CEL

PREVENTS HEAT PENETRATION

TRADE MARK REGISTERED U.S. PATENT OFFICE

A CELITE PRODUCT



Sil-O-Cel C-22 (Calcined) Brick
9" FIRE BRICK LAID UP WITH FRAXITE (HIGH TEMPERATURE CEMENT)
SIL-O-CEL Prevents Heat Penetration
Sil-O-Cel C-3 Concrete

guards the Leviathan boilers from heat and power waste. This high temperature insulation was selected for such exacting service because it possesses the lowest heat conductivity of any known material. Placed between firebrick and outer shell, it saves fuel, increases capacity, maintains uniform temperature and protects the outer shell. Firebrick is laid up with Fraxite (High Temperature Cement), another Celite Product.

Sil-O-Cel Insulation is furnished in four convenient forms,—brick, block, powder and cement. It is low in cost, easily applied,—a permanent insulation.

Write for details on insulating your equipment. Specific data given in Bulletin W-6C, use the coupon.

**CELITE PRODUCTS LIMITED, New Birks Bldg.
MONTREAL, CANADA**

CELITE PRODUCTS LIMITED.

Gentlemen: Send Bulletin W-6C and explain in detail the advantages of SIL-O-CEL Insulation, how it saves fuel, increases capacity and maintains even temperatures. I am particularly interested in the insulation of

____

The **ANDERSON STEAM SEPARATOR**

will give you dry steam, under practically any working condition, at very low cost. It is one of the most reliable safeguards against the possibility of breakdowns caused by accumulation of moisture in engine cylinders or turbine casings.

The Anderson is made in both vertical and horizontal styles. Let us send you a catalogue.

THE V. D. ANDERSON CO.

West 96th St., Cleveland, Ohio

PLIBRICO is delivered only in steel containers of distinctive appearance as shown below.

PLIBRICO
JOINTLESS
FURNACE LINING

--the long lived furnace lining

A PLASTIC refractory in unbaked form that conforms to all furnace shapes and can be installed by anyone who can use a mallet. This steel container keeps it in perfect condition and identifies the only "Jointless Fire Brick"—the one-piece refractory lining that outlasts ordinary fire brick from 2 to 4 times and resists temperature to 3,100 deg. F. The way to better furnace linings is the subject of the new booklet. Where shall we send it?

Value of Business Newspapers Recognized by Daily Press

ONE of the most striking features of journalism of recent years has been the development and rapid advance of the business newspaper to a position of importance in the business world. It was found that the best way to make a paper of benefit to advertisers was to make it of outstanding service to its subscribers, and that the advertiser eventually benefited more by a paper which gave news independently and fearlessly than by one which was merely a write-up sheet, with neither news, opinions, or self-respect.

It is by aiming for this ideal of making the paper of the greatest possible benefit to the subscriber that industrial journalism has come to the honored place it now occupies in the world of business. At the present time the industrial press holds a place of commanding importance in the business life of the country. More that 1,400 papers in Canada and in the United States are in the industrial class.

The business press covers a different field to the daily press and is not in competition with it. Business papers develop a great many advertisers who later use the daily papers and magazines.

The most conspicuous proof of the importance with which the industrial press is regarded as an advertising medium is furnished by the recent action of a society of newspaper men.

Forty publishers in Chicago recently formed an association to promote the morning newspapers' interests in competition with the evening newspapers as an advertising medium. They have announced their intention of employing the business newspapers for publicity purposes in furthering their aim.

This recognition of the place and power of the specialized newspaper coming as it does from the publishers of newspapers, who know better than most people the necessity of discrimination by advertisers in selecting their publicity channels, is a striking tribute to the value of the business newspaper as an advertising medium.

These publishers realize that the business papers reach the most important men in every industry, the men whose opinions count, and who have most influence in the business world. And not only do the business papers reach these men but they are also read by them. Many business men are not great readers, but the papers which they must read—which they cannot afford not to read—are those which deal with their own business and give the news connected with it.

The following MacLean publications are all leaders in their own field and by their means you can send your sales message to the leading men in the industries they cover. All the papers are members of the Audit Bureau of Circulations, which is a hall-mark or guarantee of quality-circulation. Information regarding circulation, advertising rates and fields covered, will be furnished on application.

Detroit V-Type Stokers Selected for America's Finest Public Buildings

McKIM, MEAD & WHITE of New York, and GORDON & KAELBER, of Rochester, Architects. ALLEN S. CROCKER, M. E., Consulting Engineer.

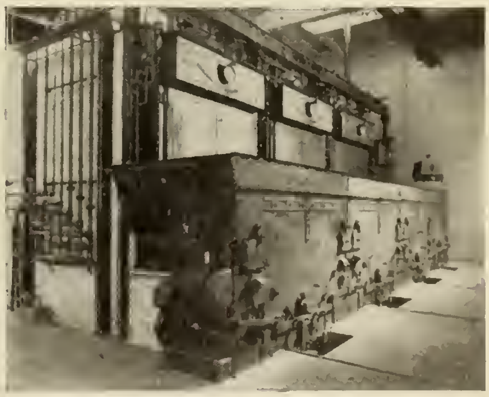
The Eastman Theater stands as a monument to motion pictures. A gift from George Eastman to the University of Rochester, the purpose of this theater is best expressed in an inscription over its portal: "Erected For The Enrichment of Community Life."

The quiet beauty of this structure leaves a lasting impression. A full appreciation of this is only secured after every feature of this theater is thoroughly known. No expense or effort was spared in the perfection of each detail. The quality of workmanship from basement to roof is of the same superb quality. The artist of every profession was given free rein to express his skill in its highest degree.

The Eastman Theater and the Eastman School of Music are connecting buildings and the one boiler house equipment serves for heating both buildings. The boiler equipment consists of three 400 horse power and one 200 horse power water tube boilers, all served with Detroit V-Type Stokers.

Thus there is added another notable structure to the long list of America's famous public buildings served by Detroit V-Type Stokers.

DETROIT NATURAL DRAFT STOKERS may be profitably installed under both tubular and water tube boilers.



Send for your copy of the Detroit V-Type Stoker Bulletin No. 338

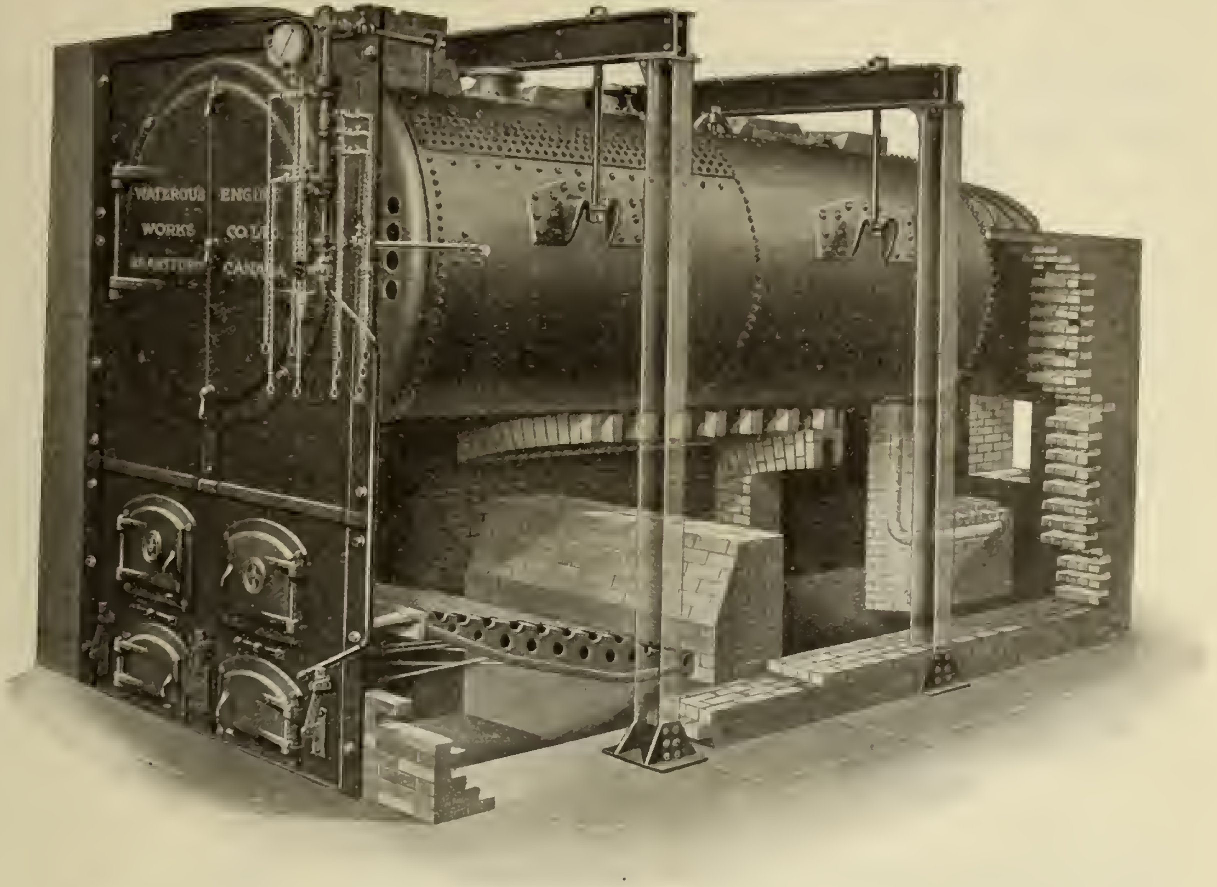
Files Stokers

Hand Operated

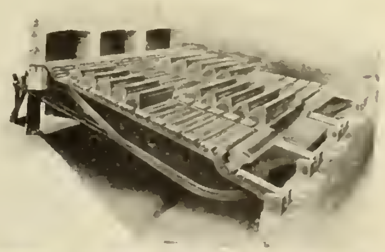


"Are Giving Absolute Satisfaction"—

S. KANN SONS COMPANY, Washington, D.C.

"In answer to your communication of Aug. 1st in reference to our **Files Stokers,** will state that they are giving **absolute satisfaction.** We have them installed under two 250 H. P. Heine Boilers.

"While we have not made a test of the actual saving in coal, would judge from 10 to 15% as our load increased 25%. We were able to carry steam without difficulty, which we could not do when our boilers were equipped with the down-draft furnaces.



"Our smoke laws in this city are very strict and with one or two exceptions we have always been able to comply with same. With careful firing there should be very little smoke. Our expense for upkeep has been very reasonable.

"Hoping this information is what you desire, we remain,

"Yours very truly,

"THE S. KANN SONS COMPANY."

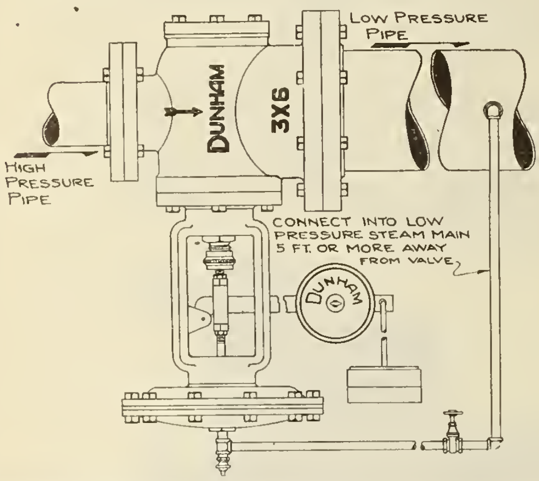
HEATING SERVICE

(Made in Canada)

Reducing Pressure Valves

The Dunham Expanded Outlet Reducing Valve shown installed in horizontal steam main is especially designed for steam heating systems which require very low pressure. The expanded outlet permits quick steam expansion and facilitates reduction from high initial pressure to as low as atmospheric pressure.



LOW PRESSURE PIPE
DUNHAM
3X6
HIGH PRESSURE PIPE
CONNECT INTO LOW PRESSURE STEAM MAIN 5 FT. OR MORE AWAY FROM VALVE
DUNHAM

Varying High Pressures Automatically Reduced to Constant Low Pressure

Dunham Reducing Pressure Valves insure an unvarying pressure on the low pressure side of the valves despite a considerable variation in pressures on the high pressure side. Steam, water or air is reduced to the desired pressure (atmosphere minimum) in one step without chattering.

Dunham Reducing Pressure Valves are applicable to a wide range of pressure service. An interchangeability of diaphragms which is permitted by standardized construction takes care of almost any pressure requirement.

Made in Straight and Expanded Outlet patterns. Finest materials and workmanship. Complete data on request.

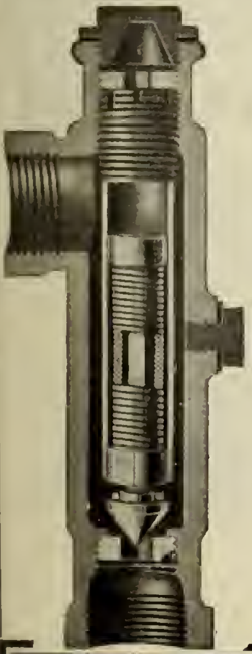
A BIG SAVING HERE

You can "make a hit with the boss" if you help him in his fight to economize in power and equipment by installing the Steam Trap Sarco.

You can then show him that you saved one-third the price it would have cost to buy ordinary traps. You can point out that you eliminated the expense of building platforms and digging pits—for the Sarco is screwed right into the pipe line. And you can explain that the Sarco will effect a big saving in fuel because, on account of its small cost, you were able to trap every point that required trapping, thus draining off all condensate as soon as it forms.



Furthermore, you can guarantee that Sarco Traps will cut down repair bills, for they have but five parts compared with as many as forty-three in some traps. Consequently, there are fewer parts to carry in stock—fewer parts to wear out and need replacement.

You can safeguard your own judgment until you are sure that the Sarco will do as claimed, as we will ship same on 30 days' free trial.

Write for particulars regarding free trial offer and interesting booklet J-31.

A Short Cut to Efficiency

Dry steam is efficient. Wet steam is not. Keep your steam dry. It goes farther—does more work. It means a saving of coal.

Cutting corners in plant economy is urgently necessary in these days of readjustment.

FISHER STEAM TRAP

(Type 33)

will rid your pipe lines of condensation. It will keep your steam dry and hot—it helps it speed along to its goal.

Extra large bucket gives it greater capacity. Shape of bucket insures a permanent water seal at all times.

Valve and seat are made of chemical-resistant monel metal. Therefore, wear is very slow. Replacement or regrinding of valve or seat is seldom necessary. From the illustration you will see the valve and seat are located at the top of trap—away from all sediment.

Let us tell you more reasons why the FISHER TRAP is acknowledged the best. Write for your copy of our interesting, illustrated book—TO-DAY.

The
Fisher Governor Company

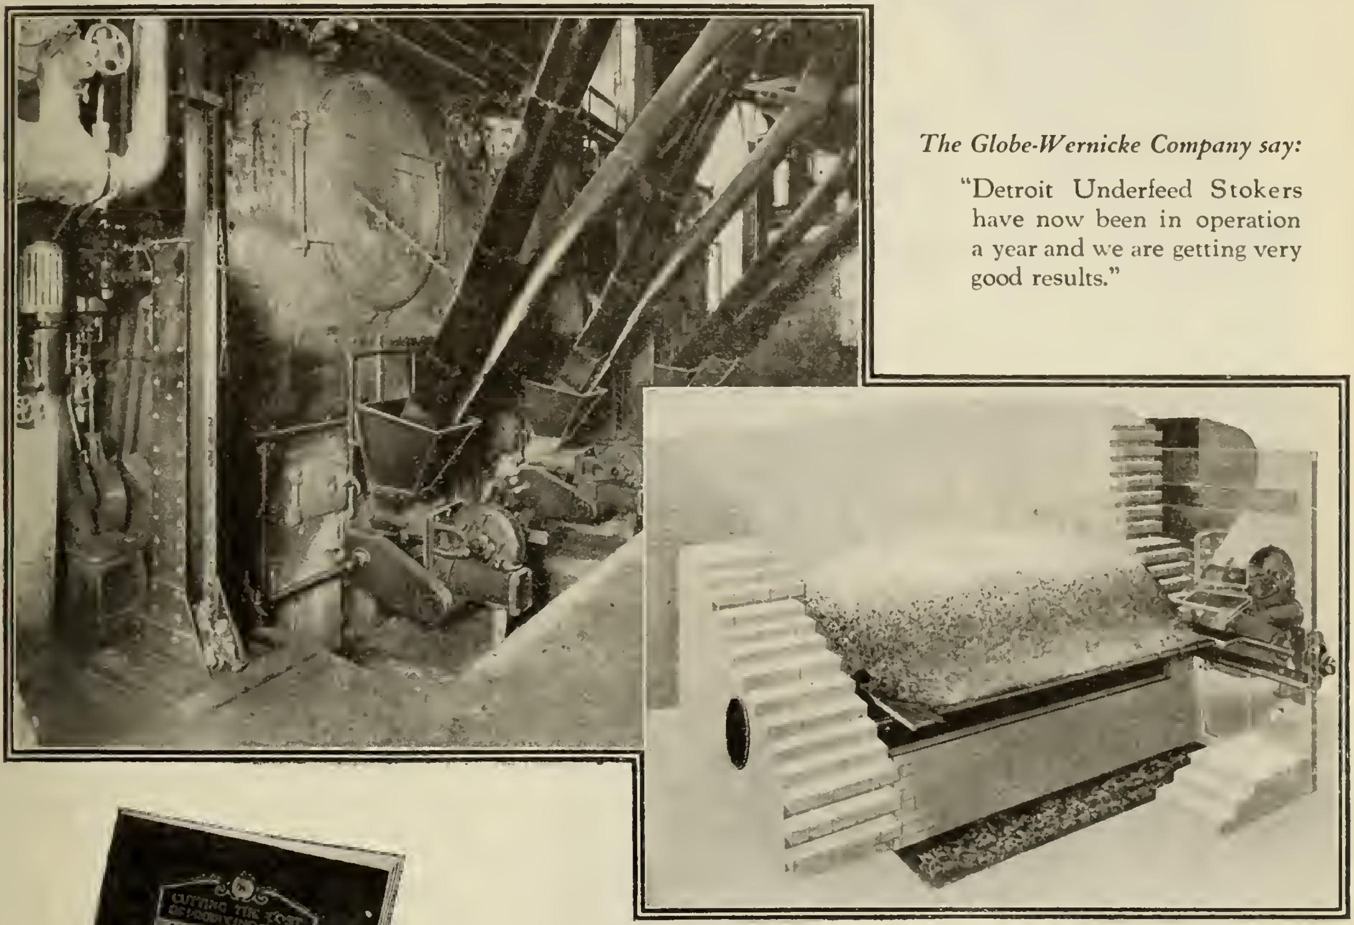
Four Detroit Single Retort Underfeed Stokers are Saving Fuel and Labor for the Globe Wernicke Company.



The Globe-Wernicke Company say:

"Detroit Underfeed Stokers have now been in operation a year and we are getting very good results."

Cutting the Cost of Producing Steam
Detroit Stoker Company Detroit Michigan U.S.A.

One of the most interesting bulletins ever put out in the power plant field, "Cutting the Cost of Producing Steam"—is yours for the asking. Request Bulletin 238.

Users of Detroit Single Retort Underfeed Stokers have found in actual practice that installation of these stokers results in the following economies:

1. *Fuel Saving:* Saves eight to twelve per cent of coal — a result due to more nearly complete combustion. Hand-fired plants average fifty to fifty-five per cent overall boiler efficiency, whereas Detroit Stoker-fired boilers average seventy to seventy-five per cent and over.

2. *Labor Saving:* Saves approximately fifty per cent of boiler room labor, depending upon plant conditions.

3. *Cheaper Coal:* Burns lower grades of fuel than is possible with hand-firing. Savings thus effected may be of such magnitude as to pay for the cost of the stokers each year.

4. *Increases Boiler Capacity:* Detroit Stoker-fired boilers may be continuously driven to much higher ratings than hand-fired boilers.

The Safe and Certain Boiler Cleanser

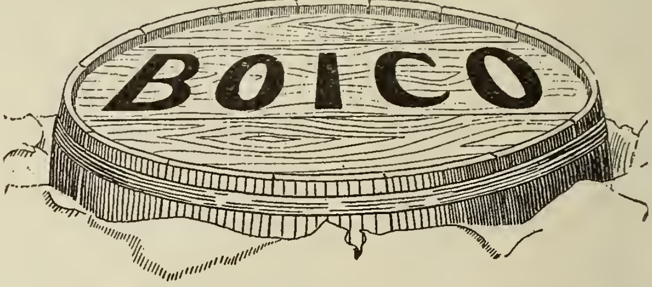
PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.**

BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.



Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

Shell-Bar Boico Supply, Limited 1-15 Saunders Ave., **Toronto**

ANTI-FRICTION METAL

MacLean Stokers

The MacLean Underfeed Stoker has been developed to give high economy in firing steam boilers under ordinary every-day operating conditions. It is simple in construction and easy to operate.

A constant uniform steam pressure is carried regardless of varying loads on the boilers.

Coal consumption is reduced.

Responds automatically to sudden demands for steam.

No siftings of unburned coal to the ash pit because there are no grates.

The steaming capacity of the boilers is increased.

Cleaner tubes and heating surfaces.

Small cost of upkeep.

A smokeless chimney is maintained with low grades of soft coal.

THE COAL IT SAVES
SOON PAYS ITS COST

MacLean Underfeed Stoker Co. Limited
95-97 King Street East, Toronto

Low Cost Pumping By De Laval Electric Driven Pumps

THE CITY of Barrie, Ont., has installed three De Laval Pumping units, two of which are shown herewith. The 4-in. two-stage series pump in the foreground delivers 600 gal. per minute against 230 ft. head when running at 1,750 r.p.m., while the single-stage pump near the wall has a capacity of 1,200 gal. per min. against 200 ft. head, at the same speed. A third pump, driven by a gasoline engine, serves as a standby or spare.

When using purchased electric power, each one per cent. gain in pumping efficiency is important. De Laval pumps not only develop exceptionally high efficiencies on test but also maintain such efficiencies for years. The labyrinth wearing rings reduce leakage, as compared with plain flat rings, and also last longer. The power taken by a De Laval pump reaches a maximum at the rated delivery, and it is not necessary to install an oversized motor in order to provide against emergency overloads, which favors higher average motor efficiency and also higher power factor with induction motors. Due to their low starting torque, De Laval centrifugal pumps can also be driven by self-starting synchronous motors. De Laval centrifugal pumps, driven by geared steam turbines, electric motors, internal combustion engines or water wheels, deliver water at the lowest total cost. Ask for Book W-100, "Ten Years' Progress in Water Works Pumps."

The YOUNG

Centrifugal Vacuum and Boiler Feed Outfit

Designed for Vacuum Heating Systems and for All Conditions Where a Wet or Dry Vacuum is Desired—Highly Efficient

This simple, inexpensive and noiseless outfit is giving very satisfactory results with Vacuum Heating Systems, Dry Kilns, Paper Driers, Feed Driers, Print Mills, Cooking Apparatus, Vacuum Pans, etc., for the purpose of effecting a saving by returning the condensate for boiler feed.

What's Behind the Door?

CONSIDER—the science of refrigeration as a universal provider and power for good in the life of the nation. Cold Storage furnishes almost the entire food supply of our modern cities.

Cold storage holdings each month run into millions of pounds of beef, pork, poultry, fish, butter, cheese, eggs, fruit, berries, milk, ice cream, etc.,—all handled and distributed with efficiency and dispatch.

And there—everywhere—stands the **cold storage door,** a guardian of purity and wholesomeness; a silent sentinel barring the ingress of heat and contamination, aiding in the conservation of refrigerating energy and effectiveness.

Remember—"Your plant is only as good as your **door,"** hence it happens that most good plants are equipped with Jamison Doors. There is a Jamison Door for every need, each bearing the mark of merit as shown above, known as "The Seal of Satisfaction."

Architects and Engineers

Jamison Coolers and Freezer Doors, Cold Storage Windows and Automatic Ice Chutes, built in standard sizes and to specifications, meet every requirement of the most exacting demands.

Seventeen years of accomplishment in the perfection of cold storage doors are pictured and described in "Jamison Booklet No. 10." Write for it.

LUNKENHEIMER
Gate Valves

embody the two essential factors most important in the engineering field—service and economy. Correct design, materials specifically adapted for valve service, unexcelled workmanship and renewability of all parts inclusive of the seat rings, insure the maintenance of these two factors.

The disc is perfectly guided by machined ribs within the body, eliminating dragging of the disc upon the seats; the renewable seat rings are solidly backed and are not dependent upon a frail face flange to withstand the wedging action of the disc; the stuffing box is repackable under pressure when the valves are full open and the stem operates in bronze bushings throughout, eliminating corrosion and insuring ease of operation.

Lunkenheimer Gate Valves are furnished in Bronze, Iron Body Bronze Mounted and Steel Monel Mounted Patterns. They are procurable in either Inside Screw, Stationary Stem or Outside Screw and Yoke Rising Stem Patterns.

Catalog 58-DC illustrating and describing the complete line of Lunkenheimer Products, will be sent upon request.

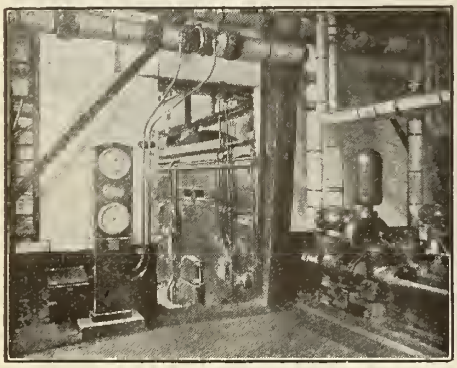
What Is Going On In Your Boiler Plant?



With fuel both scarce and costly, this is the question many an owner is asking his Chief Engineer. It is an important business which is carried on in the boiler plant and must be given serious attention. Accurate information of the evaporation of water for the amount of fuel burned each day is essential.

The VENTURI Meter

"VENTURI" Registered.

is furnishing this information in thousands of boiler plants. Over twenty years of service has proved the Venturi to be supreme for boiler feed measurement. It has long since been accepted as the Standard Meter for the boiler room.

How Much Coal Are You Wasting?

Blindfolding yourself to the fact that your boiler room is different, because you can see no pipe line leaks, or the water alarms don't blow very often—doesn't help to pay for the needless fuel waste caused by the invisible losses within the boiler furnaces.

Get at the REAL FACTS and at the same time give your men a positive and simple guide that will enable them to keep the plant at top notch efficiency—by installing the

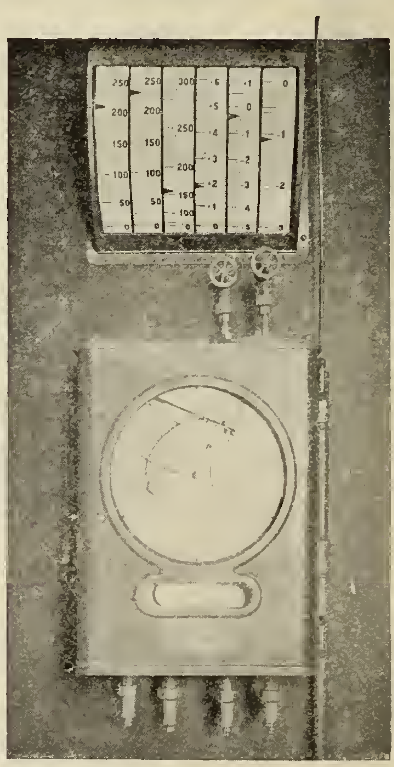
BAILEY BOILER PANEL

The Bailey Boiler Panel is a combination of the Bailey Multi-Pointer Gage and Bailey Boiler Meter.

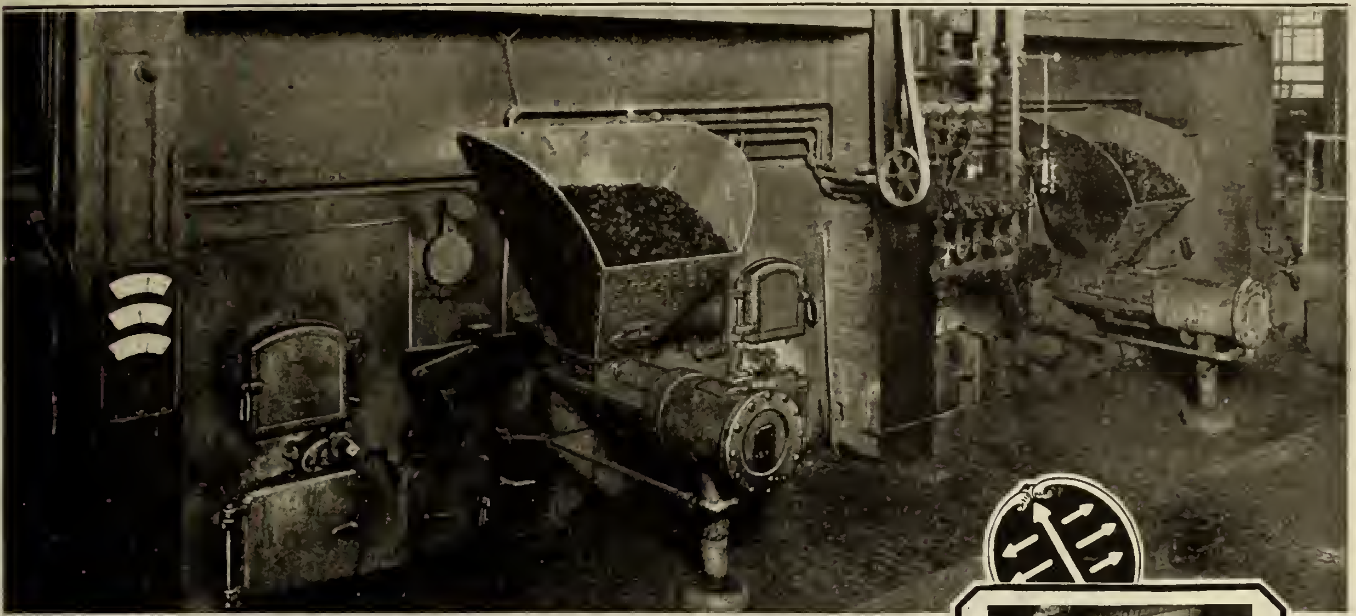
It shows, almost immediately, the effect of improper furnace adjustment and enables the men to make the necessary correction before a large amount of preventable fuel waste has taken place. Good work on the part of the men is shown up by the charts as well as any inattention. The engineer can check the efficiency of his men as well as that of the individual boiler.

Let us send you fully descriptive Bulletins.

BAILEY METER COMPANY Limited
177 DELORIMIER AVE. - MONTREAL, QUE.



The only multiple retort side cleaning stoker



BEFORE the development of the *"Lateral Retort"* Stoker there was no stoker that combined the ease of installation of the side cleaning stoker with the high efficiency and overload capacity of the multiple retort type. Plants that did not consider the expense of the multiple retort type justifiable were forced to install inferior stokers.

Now the *"Lateral Retort"* has changed all this; now any plant can have multiple retort stoking!

This simple, single retort stoker rivals the efficiency and capacity of the multiple retort type; the illustration opposite and the description below it show how the high duty service of the multiple retort is obtained.

And yet the *"Lateral Retort"* can be installed at a fraction of the cost of a multiple retort. There is no need for basement ash pits; trenches 6 to 18 inches below the floor line are sufficient excavation. This makes the *"Lateral Retort"* easily adaptable to boilers already in service and does away with the maintenance costs of complicated ash discharging and dumping systems.

The new 8½x11 standard filing size bulletin describes this revolutionary stoker in detail—and shows illustrations of successfully operating plants in the United States and Canada. Your copy is ready—ask for it.

How it works—

IN the **"Lateral Retort"** the coal follows the path of the arrows in the view above. It is underfed to the main retort—along the path of the large arrow—by a simple steam driven ram. An independently controlled moving unit underfeeds the fuel into the **"lateral retorts"** that branch off at right angles from the main retort. The ash is finally deposited on perfectly balanced dump plates easily operated by hand. The ash is dumped into shallow ash pits 6 to 18 inches below the floor line.

High air cooled front and rear tuyere blocks keep fire and clinker away from the front wall and bridge wall, practically eliminating clinkering and reducing furnace maintenance. Plate tuyeres that form the sides of the retorts reduce sifting and lower replacement costs.

Plant and Equipment of Trail Smelting Works

Method of Separating the Metal From Impurities by Electro Chemical Process—Pumps, Machinery and Electrical Equipment That Constitute the Makeup of This System

By Geo. R. ARCHDEACON, A.M.I.E.E.

AMIDST the snow-capped mountains of British Columbia, on the Columbia River, 45 miles from Nelson, B. C., is the thriving town of Trail with a population of nearly 4,000 people. Above the town, some 300 ft. is the plant of the Consolidated Mining & Smelting Co.

This Company, of which S. C. Blaylock is manager, is one of the most unique and completely equipped smelting plants in America, if not in the whole world. Certainly, there is no other smelter in existence which smelts and refines gold, silver, copper, zinc, and lead. The company have devoted separate buildings for each of the above mentioned metals, and each metal therefore is provided with a special set of buildings in which it passes through its course of treatment. This naturally involves a separate staff for each metal, and the staffs therefore, becoming highly specialized in the production of these metals.

The refining process is an electrolytic process, and naturally demands the employment of very large volumes of electrolytes, consequently the company have erected a special chemical plant in which the necessary electrolytes are manufactured. Furthermore, as these electrolytes, become contaminated with the impurities from the metals, provision had to be made for treating the used electrolytes, and freeing from all impurities accumulated in their course of refining the virgin metal.

Some idea may be gained of the immensity of this department, from the size of the building in which the contaminated electrolyte is treated. The building which is devoted to this purpose covers an area of two acres.

Other departments are on an equally large scale. On account of the total absence of any local machine shop or foundry, the company had to engage in this business as a sort of a "side line" to enable them to quickly effect any repairs to their extensive plant and equipment. The machine shop, foundry, and electrical repair shop, form a set of buildings considerably larger than most businesses entirely devoted to this class of work. The equipment includes, one 25 ft. lathe, with a 10-ft. face plate handling 7-ton castings; two Brown and Sharpe shapers, and one 36-ft lathe with 5-ft. face plate, boring mills, planers, profilers, radial drilling machines, electric and pneumatic portable drilling and riveting machines.

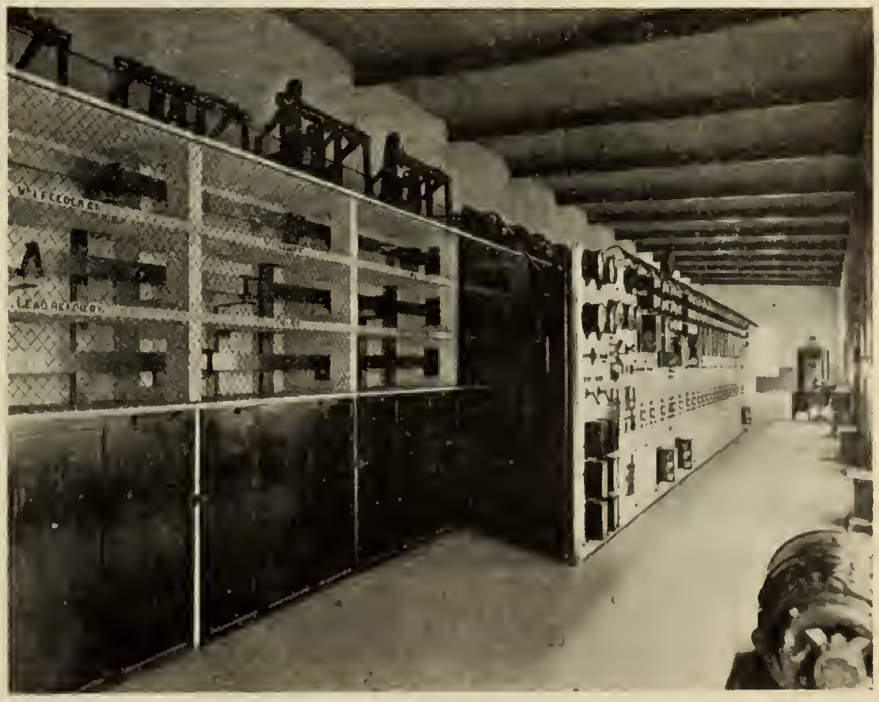
Although the company went to considerable expense to equip these repair shops, they now find that these repair shops not only provide them with a sure and quick source for repairs, but the prices charged to each department using these shops, although about 10 per cent. lower than could be obtained, are sufficient to show a very considerable dividend on the investment, after making the usual provision for depreciation, etc., and the various items of overhead usually associated with a machine shop.

The process of refining is strictly an electro-chemical one and is briefly as follows—

The impure metal is made the anode (positive pole) of an electrolytic bath, the electrolyte of which is a solution of the pure salt of the metal to be refined, whilst the cathode (negative pole) is a sheet of the refined metal.

On passing the current, metal dissolves, along with certain of the impurities. The impurities, which are electro-negative to the principal metal, dissolve; those electro-positive to the principal metal, remain adhering to the anode. When the latter finally drop off from the anode they may be dissolved by free acid; in which case they would be precipitated as an insoluble salt as soon as they dissolve, and are thus removed from the further action of the current.

When it goes into solution, the principal metal is therefore separated from those metals which are electro-negative



No. 1—Main switchboard, showing arrangement of bus-bars with their open panels.

with respect to it. When it is deposited on the cathode, it is separated from those metals which are electro-positive with respect to it. The bath thus becomes contaminated with certain impurities in the anode and these would eventually become deposited on the cathode if the bath is not purified from time to time.

In each department devoted to the refining of a special metal, the metal to be refined is fixed in a large tank, which resembles a storage battery. There are thousands of these large tanks to be observed, all connected up something like a storage battery, and receive a supply of direct current in a similar manner to the charging of a storage battery.

The amount of current required varies from 10 amperes per sq. ft. of cathode surface, to about 30 amps. per sq. ft., depending upon the metal being refined.

The voltage required per bath varies from about 0.30 to about 3.5 volts, depending again upon the metal being refined.

It will readily be seen, therefore, that a large amount of electrical energy must be consumed by a plant of such large proportions, but one is amazed at the figures given. The amount of electrical energy consumed for December, 1922, was 14,772,500 K. W. H.

To provide for such huge demand for power the following electrical plant is required.

Total of motors installed ...30,000 h.p.
Total cty. of motors installed 30,000 h.p.

This power is generated at Bonnington Falls about 33 miles from the smelter.

This power comes in to the smelter by two systems:—

(a) 3 phase 60,000 volts, 60 cycles.
(b) 3 phase 20,000 volts 60 cycles.

It is received by two banks of transformers arranged in set of 3 and each set is isolated in a separate room; the current leaves the transformers at 2,200 volts, and goes direct on to the main bus bars, then through the main switchboard and from there distributed to the various buildings. Illustration No. 1 shows the excellent arrangement of the bus bars with their open front panels, permitting full view and plenty of space in which to effect repairs if necessary.

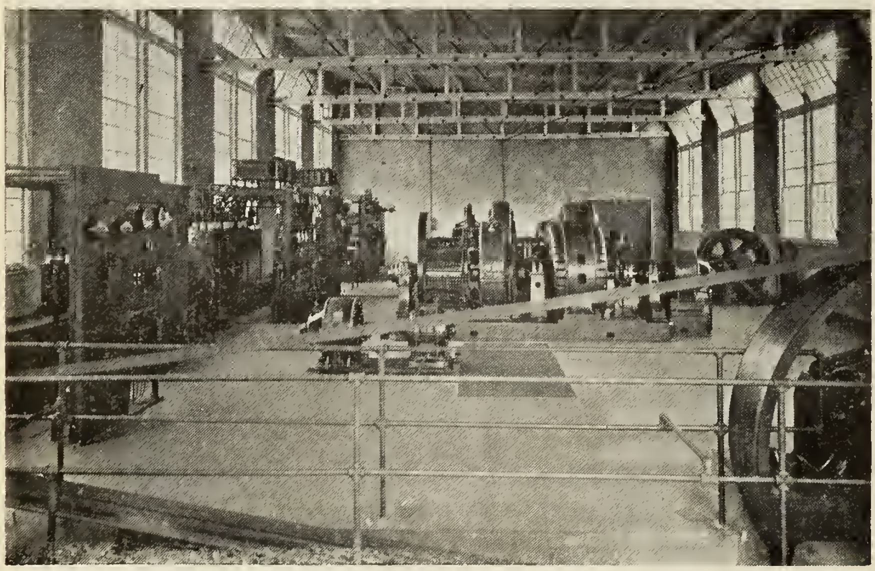
In the main sub-station of the plant, there are 13 motor generator sets, each one operated by a synchronous motor 1,475 h. p. at 2,200 volts, 60 cycles, 3 phase direct coupled to 2 d. c. generators 500 k. w., 50, 125 volts 4,000 amperers at 600 revs.: Six of these motor-generator sets were manufactured by the Canadian Westinghouse Co., and seven of them by the Canadian General Electric Co.

For operating the smelting furnaces many blowers are required and are located in a large blower room. In this room there are arranged: 1 400 h.p., 1 600 h. p., 2 300 h.p., 1 200 h.p., blowers, belt driven by electric motors, and 1 900 h.p. Ingersoll-Rand turbo blowers direct coupled to electric motor.

Several miles of narrow gauge railway track are laid in the yard, and are operated by small electric trolley cars. There are 25 electric trolleys in constant service to maintain the traffic on these lines and this in turn requires 2 300 h.p. motor generator sets for supplying the current to the trolleys.

It is most important that there should be no interruption of the tilting of the cupolas when the metal has arrived at the correct temperature. Should this movement be interrupted at the critical moment, about 70 tons of metal and ore would be ruined. To guard against such a calamity a storage battery has been installed. This consists of 125 cells of 19 plates per cell, contained in large glass jars, the capacity of which is 800 ampere-hours at the 8-hour rate of discharge.

This battery daily receives a "freshening" charge, and consequently is always in a condition to maintain its voltage during a complete discharge. It is so connected, that in the event of the electric power suddenly failing, an automatic switch puts the battery in circuit with the motors operating the tilting gear on the cupolas, and will tilt the cupolas as required, and so prevent any loss of metal.



No. 2—Corner of the Main Sub-Station.

Submerged Pumping Station

An interesting development in connection with the power supply to the smelter is a submerged pumping station. The plan was to pump the water from the Columbia river, and at such point above the town that the water should be quite pure and uncontaminated. This point was finally located about a mile up stream from the smelter as already mentioned. The smelter is about 300 ft. above the river, therefore the pumping of large volumes of water to this height necessitates considerable expenditure of power.

Another difficulty presented itself however, in the varying height of the river, since at this point in the river the rise and fall of the water level is about 50 ft., this being due to the change in seasons. With such differences of level, it was impossible to install an ordinary pumping plant, as the lift would be too high in one season, and the pumps would be flooded during the following season.

The company's engineers have overcome all these difficulties, and have constructed a pumping station of great strength and permanence, at a point low enough to draw up the water, whilst at its lowest stage, with a sloping tunnel entrance running from a point up the river bank high above the highest known water mark, the whole being covered over and made absolutely water-tight.

Through the bottom of the pumping house, three steel pipes, 10 inches inside diameter, lead outward and downward into a covered forebay from which the supply of water will be drawn The whole structure is of reinforced concrete, and is of massive and solid construction, this being necessary on account of the great pressure exerted by the water during its higher levels, which will entirely submerge the pumping station to a depth of about 35 feet.

The station is accessible at all time by the sloping tunnel, the entrance to which is high above the highest known water level. This tunnel also accommodates the 16-inch main delivery pipe from the pump to the smelter some 250 feet higher up the mountain side.

The details of construction are as follows:—

Building is reinforced concrete and water-tight 20 ft. by 30 ft., with an arched roof 14 ft. in height.The tunnel is about 90 ft. long and 7 ft. high by 9 ft. wide.

Pumping installation consists of three 10-inch centrifugal four-stage pumps made by Goldie & McCulloch, Galt, Ont. These pumps have a 10-inch suction and discharge pipe, the discharge of each pump converging into the 16-inch main. Each pump is directly connected to a 200 h.p. electric motor. In addition, there is a small 3-inch sump pump, for the pumping out of the building in case there is any seepage of water into the building.

This pumping plant is certainly unique. It is splendidly conceived, well constructed, and does credit to the engineers of the smelter who have the responsibility of developing this plant as their business increases.

The chief electrical engineer is A. H. Hopkins, A. I. E. E. and member of the Society of Professional Engineers of British Columbia. Mr. Hopkins is an Englishman, having been born in Gloucester. He served his articles with H. E. Neil, contracting engineer in London, Eng., and has specialized in the application of electricity to smelter plants. He has occupied positions in charge of the electrical equipment of the following concerns: B. C. Copper Co., Boundary Falls Smelter Co., and his present position with the Consolidated Smelting and Refining Co. which he has occupied for four years.

Mr. Hopkins has installed a system, which might with advantage be copied by engineers in charge of industrial plants where large numbers of electric motors are in operation. The method is simple, easy, and cheap to operate.

Each motor on the plant is given a card. Upon this card are the full details of the motor, also special details concerning the type of winding, such as wave or lap-wound, number of turns per slot, number of slots, etc. This prevents any delay in pulling it down to get this information, in the event of an armature coil being burned out, and a rush call being sent for spare coils, etc.

On the reverse side of the card are special rulings for date of inspection, condition, and name of inspector. By this method every motor on the plant has a complete record which can be turned up. This permits a detailed history of each motor being kept, and any incipient fault can be carefully watched, and the necessary repair effected before it reaches a final breakdown. It furthermore provides a true indication as to the wearing qualities or other merits of spare parts, renewals, etc., supplied by competitive companies.

In a place somewhat removed from the busy life of the large cities, it is an important work to see that the necessary labour is at all times available. This is still more imperative when considering the subject of skilled labour.

The smelter has therefore instituted a system of apprenticeship. A boy after leaving school may become an apprentice in the electrical shop receiving a merely nominal salary. There he receives instruction in the entire workings of a large electrical repair shop, covering such important subjects as armature winding, armature building, coil making, insulating, winding of transformers, erecting of heavy switch gear, general details of wiring for light and power, testing and fault localization.

Such a course is remarkably comprehensive, and is a most valuable experience, one that appears to be well appreciated locally. The apprentice must gradually pass through his grade, from apprentice, improver, 2nd class electrician, 1st class electrician. His progress and remuneration rest entirely upon himself, and depends how seriously he applies himself to the subjects above mentioned.

By this method the company have not to depend upon the transient worker who may be making his way from one city to another, as they have a ready source of good material to draw from and by making their work interesting, and providing real opportunities for progress, the sense of local patriotism is aroused, and the utmost loyalty is developed, resulting in advantages to the smelter that cannot be gauged in mere dollars and cents.

S. C. Blaylock, general manager, is a graduate of McGill University, Montreal, and is a chemist and metallurgist of distinction. Coupled with these scholarly accomplishments, he possesses that still rarer virtue of being able to inspire great zeal in all of his subordinates, ever keeping before them the achievement of some great accomplishment, and at the same time maintaining that co-operation amongst his 1200 employees that makes work pleasing and agreeable to them all, whilst he himself has gained the respect of all his workmen in a manner that is only to be expected.

Air Compressor

A new type of compressor unit which is comparatively small and compact for its capacity has recently been placed on the market. The cylinder and oil reservoir are integral with the base casting, which makes the appliance exceptionally rigid. The two cylinders extend horizontal through the length of the casting. The valves are located in the heads of the cylinders and are of ample size to prevent overheating. The valves are of steel, bearing against cast-iron seats, and have a 30 deg. angle. The pistons are of the double type, one located at either end of a connectiong section. The piston is operated by means of a hollow eccentric shaft that fits into a bronze bearing of large diameter. This arrangement eliminates the use of piston pins, crank bearings and connecting rods. Piston rings are provided at both ends to prevent the loss of compression. All bearings are made of bronze. The main shaft bearing is fitted to the side of the cylinder casting and the other end is supported by a small bearing within the cylinder. Forced-feed lubrication is used for all bearings, the small plunger pump drawing the oil from the reservoir in the base. The oil is delivered through the hollow main shaft and thence through small openings to the different bearings. The lubricating system is entirely automatic. These electric compressor units are made in various sizes, ranging in capacity from 1¼ cu. ft. to 3¾ cu. ft. of air per min., the last named rated at 250 lbs. pressure. The automatically controlled tank units are made in two sizes, one working at a pressure of 150 lbs. per sq. in. and the other at 175 lbs. per sq. in. These machines are made by the George Sacksinmaier Co., Philadelphia, Pa.

Listening in with Celoron.—This is the title of a new pamphlet being distributed by the Diamond State Fibre Co., of Canada, Toronto, in conjunction with their new standard radio panels, cut to size and individually wrapped in glassine. This pamphlet includes a complete list of broadcasting stations in Canada and the United States, together with symbols found in diagrams of hookups. One of the pamphlets is supplied with each panel. New window and counter display signs are also being supplied to dealers including an attractive sign emphasizing standardized Condensite Celoron panels, with clips to hold a sample glassine-wrapped panel.

Prospects for the Development of Shale Oil

In the Event of the Supply Being Exhausted the Method That Could be Adopted to Develop the Oil Bearing Shales on a Commercial Basis

In certain applications, oil has distinct advantages over coal as fuel. In the transportation field, for example, oil-burning engines of the Diesel type have proved exceedingly useful, and the familiar internal-combustion engine, burning the lighter distillates obtained from crude oil, is known to everybody. Many of the boilers used in marine service are designed for oil burning, because the use of oil saves space and labor, and it may also reduce the time that must be spent in port. Unfortunately, apparatus that is specially designed for using oil as fuel can seldom be operated advantageously with other fuels without extensive and expensive alterations. Once embarked on a fuel-oil basis, the owner of the apparatus must look to his oil supply for maintenance, and when many owners adopt the oil-burning policy, the supply problem becomes decidedly serious.

The oil-well situation in the United States must interest and concern all of us. The United States Bureau of Mines is authority for a statement to the effect that 40 per cent. of our well-oil has already been used, and that with the increasing demand our known underground reserves will be exhausted in something like ten years. But even though this diagnosis of the situation be correct, the United States need not fear an oil famine by 1932, because we shall still possess vast deposits of oil-burning shale, which can be made to yield many times more oil than has been taken from our wells up to the present time. It is plain, therefore, that the oil-shale industry is bound to be exceedingly important in the near future, and it behooves us to study the problems that it involves, so that we shall be ready to deal with them intelligently. The principal known deposits of oil-bearing shale occur in Colorado, Utah, Nevada, and Wyoming, although there are deposits in other states also, and some of these may be more extensive than we now realize. A limited amount of it is so located that a considerable investment of money would be necessary for its development. The needed money will doubtless be available, however, as soon as the commercial practicability of winning the oil from our shale has been demonstrated. The shale-oil industry is already thriving in certain other parts of the world, and notably in Scotland; but our own problems are somewhat different from those encountered elsewhere, and they call for correspondingly individual study.

Experience and test have shown that there is a wide variation in the oil content of the shale, the range in commercially workable deposits being from 25 to 100 gallons of oil per ton. In addition there are useful by-products, the most important usually being ammonium sulphate. Certain other materials available as fertilizers are obtained, and there is a considerable yield of permanent (or non-condensible) gases, which are combustible, and which can be used, locally, as fuel. Variation in the processes that are employed for winning the oil will materially alter the proportions of the products that are obtained, and it is therefore necessary not only to have a definite knowledge of the composition of the shale that is to be treated, but also to study the exact details of the process that is used, in order to insure a maximum yield of marketable output.

The oil is driven off from the shale by means of heat, and the first process in the industry consists in mining the shale and preparing it for the retorts in which the heating is to be done. Some deposits can be worked with advantage by steam-shovel or open-quarry methods, but in most cases it will be necessary to conduct operations similar to those involved in coal mining. Longwall and room-and-pillar mining methods can both be used in working shale deposits, just as in working coal deposits; and in shale mining we may expect to encounter many of the hazards associated with the coal industry, including falls of roof, fires, and explosions of gas and perhaps of dust.

On account of the softness or plasticity of the shale, considerable difficulty has been experienced in breaking it up into sizes suitable to be fed into the retorts. It does not fracture readily, and the ordinary crusher will not handle it satisfactorily; but it has been found that panmills with rotating hammers can be made to do the work quite well.

We cannot here discuss the design of the operating retorts, nor explain why the Scotch methods are not suited in all respects to the treatment of American shales; but we may note that it is essential to design the entire apparatus so that the raw shale can be fed into it continuously, and so that the spent or exhausted shale can be withdrawn continuously. It is also necessary to provide an effective means for keeping the shale in motion in the retorts, so that it cannot fuse together and so that all parts of it will be subjected to the same temperature-treatment. The reduced (or extracted) oil-vapor should be led away and condensed as quickly as possible, because continued exposure to a high temperature tends to fix the gases permanently, and thereby reduces the marketable output.

Most shales begin to give off oil-vapor at 150 degrees Fahr., and the temperature to which the shale is exposed may be gradually increased up to 700 degrees Fahr., at which point practically all the oil has been removed. Most of it will vaporize at a temperature under 300 degrees or 310 degrees Fahr., and that which is given off below this point must be removed and condensed, to avoid permanent gasification as already noted; but it may be important to raise the temperature of the partially exhausted shale still further, in order to obtain all the combustible elements that it can give off. By the time our American shales have been heated to 700 degrees Fahr., they give off, on an average, about 3,000 cubic feet of permanent gas per ton of shale retorted. Operating at higher temperatures will increase the amount of fixed gas and reduce the amount of oil; and an easy and accurate method of controlling the temperature of the retorts is therefore essential to the successful recovery of shale oil, on a commercially profitable scale. There is seldom any market for the permanent gas that is produced, and such gas must therefore be used at the plant or be allowed to go to waste. The fixed gas is likely to average more than 400 British thermal units per cubic foot of gas, or 1,200,000 such units per ton of shale. Less than half of this amount of heat is needed for retorting one ton of shale, and unless the remainder can be used advantageously about the plant, it may be more economical to stop distillation before the 700 degrees temperature is reached. The exact limiting temperature for maximum profit will depend in considerable measure upon the needs of the plant for gas as fuel, in comparison with the quantity of oil obtained from the shale.

As the hot vapors are led away from the retorts, they pass through water-heaters, condensers, and separators—apparatus similar to that used in handling the vapors produced in by-product coke-making. The vapors emerge from the separators as crude oil, fixed gas containing naphtha and ammonia, and steam impregnated with ammonia. The ammoniacal steam is condensed, and the permanent gas is scrubbed in a tower by means of a waterspray—the ammonia water that is obtained in this way being added to that obtained by direct condensation, and the ammonia being recovered from the whole in the form of

Boiler Room Appliances and Auxiliaries

Development of the Boiler Room From Its Earliest Stages, Showing Approved Appliances Relative to Safety and Economy —Easy Present-Day Methods Compared With Those Used Earlier

By W. B. ROBERTS

IT IS a very interesting study to follow the development and progress of the power plant from the days of the Newcomen engine in 1712, to the establishment of the modern up-to-date plant. Although progress for the first half century was very slow we had in the Watt engine a development in the application of steam that is the principle and basis of the present day engine, although in most cases these are so vastly different in design, that they can hardly be recognised as a development of the same machine. As the Newcomen's atmospheric engine was practically the first engine of any consequence operated by steam, it will be rather interesting to look into the merits of this engine as a means of comparing it with that of Watt's engine.

The principle of this engine was that steam upon being condensed contracted, thereby causing a partial vacuum. If therefore we have a vacuum on one side of a piston and the atmospheric pressure on the opposite side, the piston becomes unbalanced and we get a condition that is likely to produce work providing there is sufficient difference between the pressures on both sides of the piston to overcome the friction of the machine. It will be seen upon looking at Fig. 1 the general arrangement of this engine and how the motion is actually produced. Steam is generated in the boiler B at a very low pressure and is admitted through the valve S. V. into the cylinder C. A jet of cold water is sprayed upon the steam, the water having gravitated from the tank C. W. T. through the down pipe and regulated by the injection cock I. C. This condenses the steam, causing a partial vacuum in the cylinder. The piston therefore, being exposed on the one side to the atmosphere, is forced downward due to the difference in pressure on each side of the piston. At the end of the stroke, the weight of the rods at the opposite end of the beam, raises the piston to the top of the cylinder again ready for a repetition of the operation. We will therefore see that in this old and discarded form of steam engine, the pressure and expansive properties of the steam were not utilized or taken advantage of in operating the engine, as the steam was only used to condense and produce a vacuum. The waste of heat through the initial condensation, due to the steam entering the cold unprotected cylinder, must have been very great.

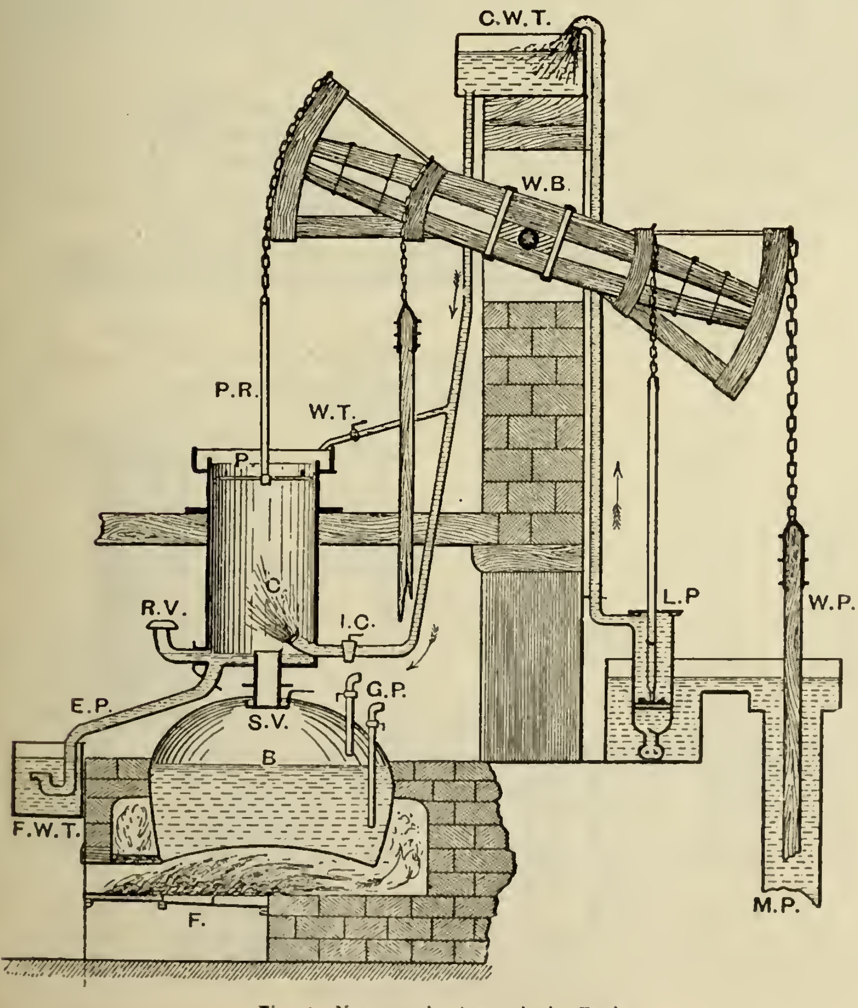

Fig. 1—Newcomen's Atmospheric Engine.

Although it will be realized that the demand for fittings and auxiliaries in a plant of this description was comparatively small, it would be interesting to know just what fittings were used. The illustration which was taken from a very old cut of a boiler of this type, shows two gauge pipes G. P. and a relief valve or snifting valve R. V. which valve would no doubt also act as the safety valve to the boiler. If however, this latter valve was set too rigid or jammed at any time, the pressure in the cylinder C could never exceed the pressure due to the head of water from the tank C. W. T. as long as the cock I. C. was open. These seem to comprise the total fittings of this engine.

In the Watt's single acting engine made in 1769 and illustrated in Fig. 2, we have an engine working on a different principle. In this case, although the piston-rod is connected to a chain on a quadrant similar to that of the Newcomen engine, the engine it will be noted, is detached from the boiler and the cylinder is closed at the top end. This enables the steam pressure to be directed against the top of the piston P. whilst the vacuum on the lower side of the piston, due to the steam being condensed in the condensor J. C., reduces the back pressure, thereby making the steam on the top of the piston more effective. In an engine of this description, it will be seen the necessity for additional appliances the principal of which, as far as the engine is concerncd, are the separate condensor, also the air and feed pump. This engine would be much more economical than the Newcomen enigne at the same time we can see it becoming more complicated in design. This renders it necessary to have a more complete record of our temperature and pressures at the different phases through which the steam passes.

The next great development in the steam engine was fifteen years later

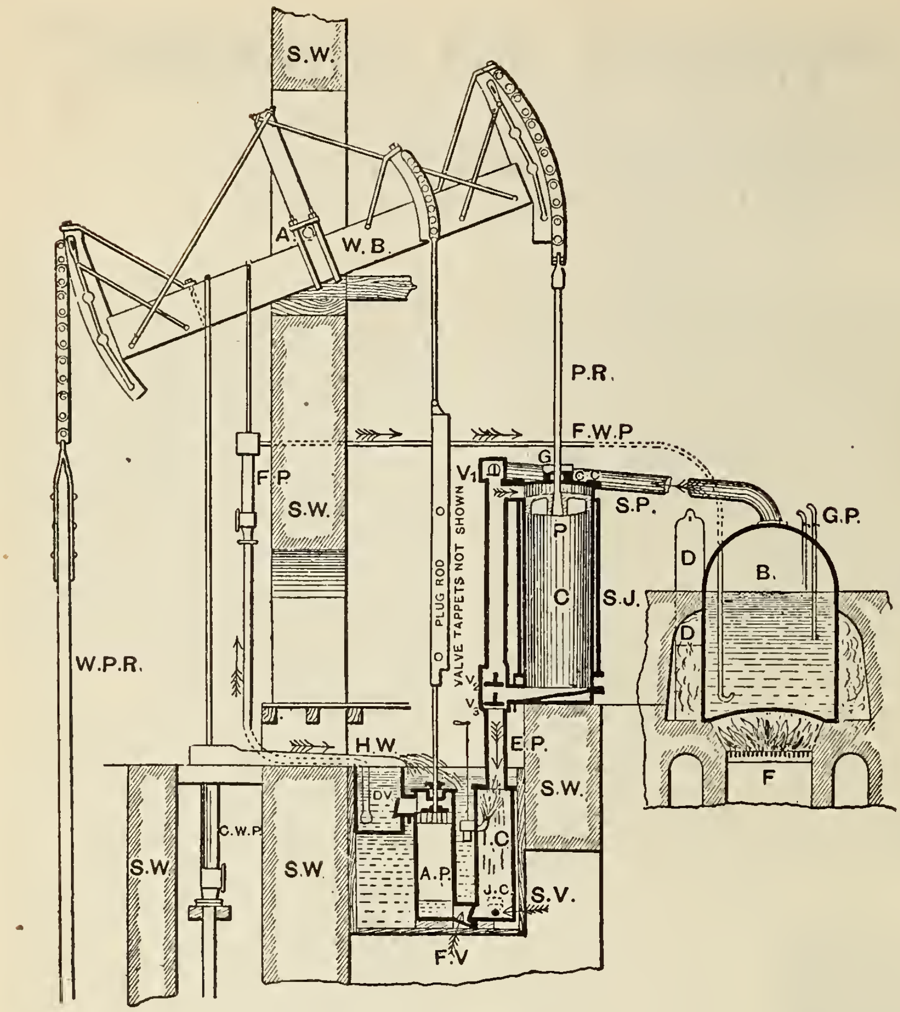

Fig. 2—Watt's Single Acting Engine.

when, in 1784 Watt invented his double acting single cylinder beam-engine, it will be seen the great improvements that were made upon his earlier machine, with the introduction of the piston rod, fly-wheel, better cylinder arrangement, and the governor and throttles valve. The steam and exhaust valves for the top and bottom of the cylinder are operated by the four tapped rods T. R., which are attached to the air pump rod and connected to the beam. It will be seen that the principle of this engine is much in common with the present day engine, except that the design has to be very materially modified, on account of using such high pressure steam compared with that used 150 years ago and also the extremely high speed of engines that are used these days compared with 20 revs. pr. m. which was a very common speed for engines of this description at that time.

Evolution of Steam Boilers

It is needless to say that during the development of the steam engine, corresponding progress was also made, in the development on the steam boiler. During the process of evolution, there is no such thing as rest. This would be amply demonstrated to anybody who cared to visit the Patent Records office, where they would find thousands of boiler designs patented, 95 per cent. of which would fall down very quickly upon being put through a vigorous examination. A favourite form of boiler that was much used during the early part of the eighteenth century was the externally fired egg-ended boiler. This type of boiler, however, became very unpopular owing to the number of explosions that occurred due to the ripping of the seams that formed the ends. The Cornish & Lancashire boilers were two class of boilers that were introduced to meet a certain need and are still a very popular form of boiler in Great Britain at the present time on account of the great abuse these boilers will stand. They are usually to be found in such places where we find the Horizontal Return Tubular boiler in this country.

There are also quite a large number of boiler types that are used for special purposes such as Scotch or marine type boilers: Locomotive Galloway Cochrane & Vertical boilers all having their own particular merit, but in each case the object seems to be to increase the heating surface without materially affecting the size or cost of the boiler.

The water-tube boiler has received a great amount of attention of late years, on account of it being a much safer type of boiler for use with high pressures, and furthermore, being a quick steamer, it is in a position to handle a sudden demand for steam almost instantaneously. This is a requirement demanded from boilers both in electric generating plants, fire stations, and also one that is indis-

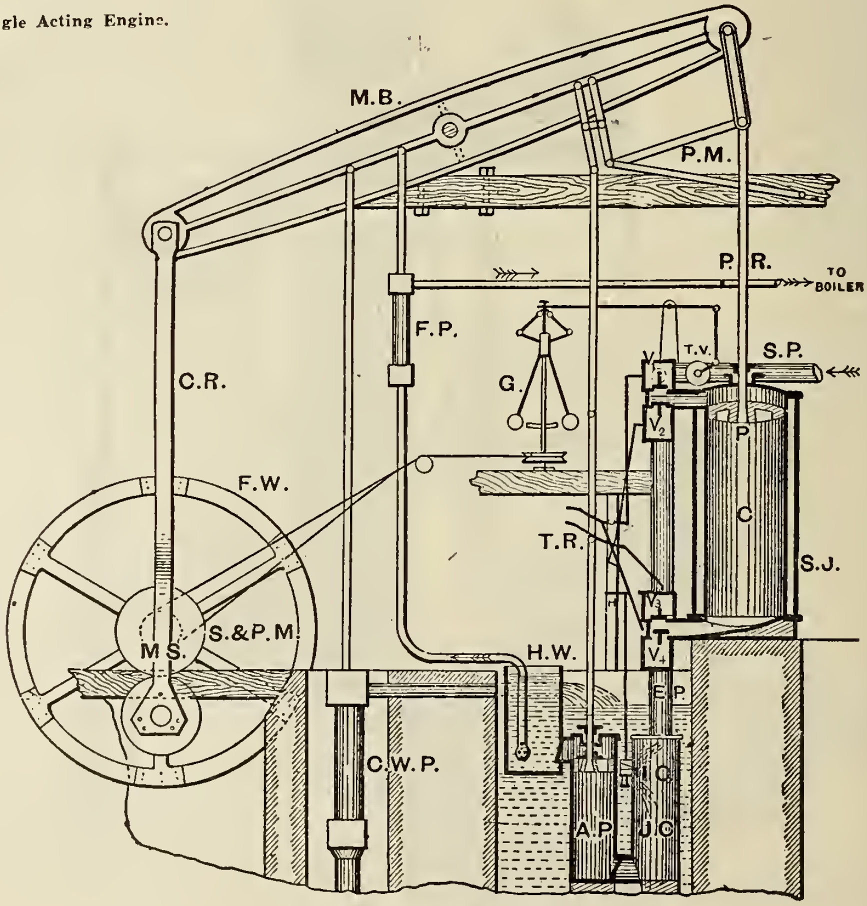

Fig. 3—Watt's Double Acting Engine.

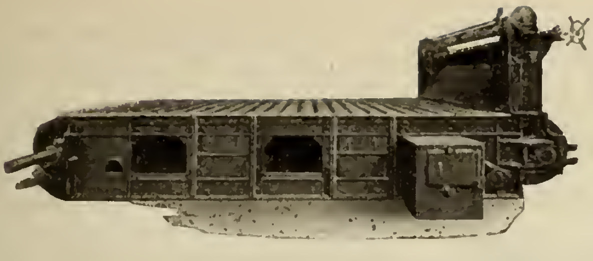

Fig. 4—Coxe Chain Grate Stoker.

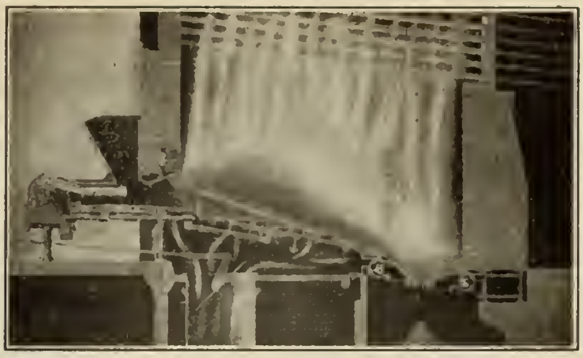

Fig. 7—Open Induction Feed-water Heater.

pensible in naval vessels. If you look at any standard design in this type of boiler, you are looking at a boiler that has stood the test in the process of evolution, and not some chance design that has been hit upon by some fortunate engineer. The number of water-tube boilers that are so similar in appearance, are numerous, but when you come to look into the merits of each, you find there is a structional weakness or economical drawback somewhere in its constitution. The water-tube boilers that we are familiar with at the present time, are the result of the "survival of the fittest" and although it may not be perfect, it is the ultimate result of many years of experience and tests as far as the design is concerned. The engineer demands that his boilers should be safe, efficient, economical as far as fuel and space is concerned, and to be economical they will of necessity be high pressure. Even with the high pressure steam that we are using these days, compared with that of fifty years ago, there is nothing like the number of boiler explosions now, as compared with those days. The safety appliances that we have in the form of fusible plugs, safety valves, high and low water alarms, automatic cocks to the glass water gauges, test cocks and the score of other arrangements and fittings, all help to reduce the possibility of a boiler accident as far as the mechanical equipment of the boiler is concerned. Our engineers are also trained to understand the theory and design of boilers, which in combination with the rigid system of examination that is forced upon the boiler owner by the various Provincial Governments, and also the further examinations that are given at a very nominal figure by the boiler insurance companies, the possibility of a boiler explosion is reduced to a minimum.

First Stages to Promoting Economy

When we come to look into the early methods of generating steam and compare the equipment with that used at the present time, we cannot but realize that their methods were most extravagant and offered great opportunities for improvement. The necessity for this very naturally inspired the engineer of that day to devote much of his attention to promote better and more economical operating conditions. The lost heat in the flue gases was a very favourite spot chosen by engineers with a view to recover some of the heat units by introducing an economiser for heating the feed-water. However there is only a certain amount of heat that can be recovered from that quarter and anything above this amount is going to very materially affect the draught of the stack, and therefore have a detrimental effect upon the operation of the furnace.

Stoker Design

It was realized at a very early date that great improvements were possible in the furnace design with a view to promoting greater economy in the combustion of the fuel. In 1819 Brunton designed a travelling grate, which is said to be the first mechanical stoker brought out in England. Numerous improvements were made on this type of stoker from time to time, and that form illustrated in Fig. 4 is one of the first of this type to be used with forced draught. In 1838 the first underfeed single retort stoker was patented by Jukes, which is an arrangement wherein the coal is thrown into the hopper and allowed to drop down in front of a ram. The coal is then forced under the centre of the grate below the burning fuel by means

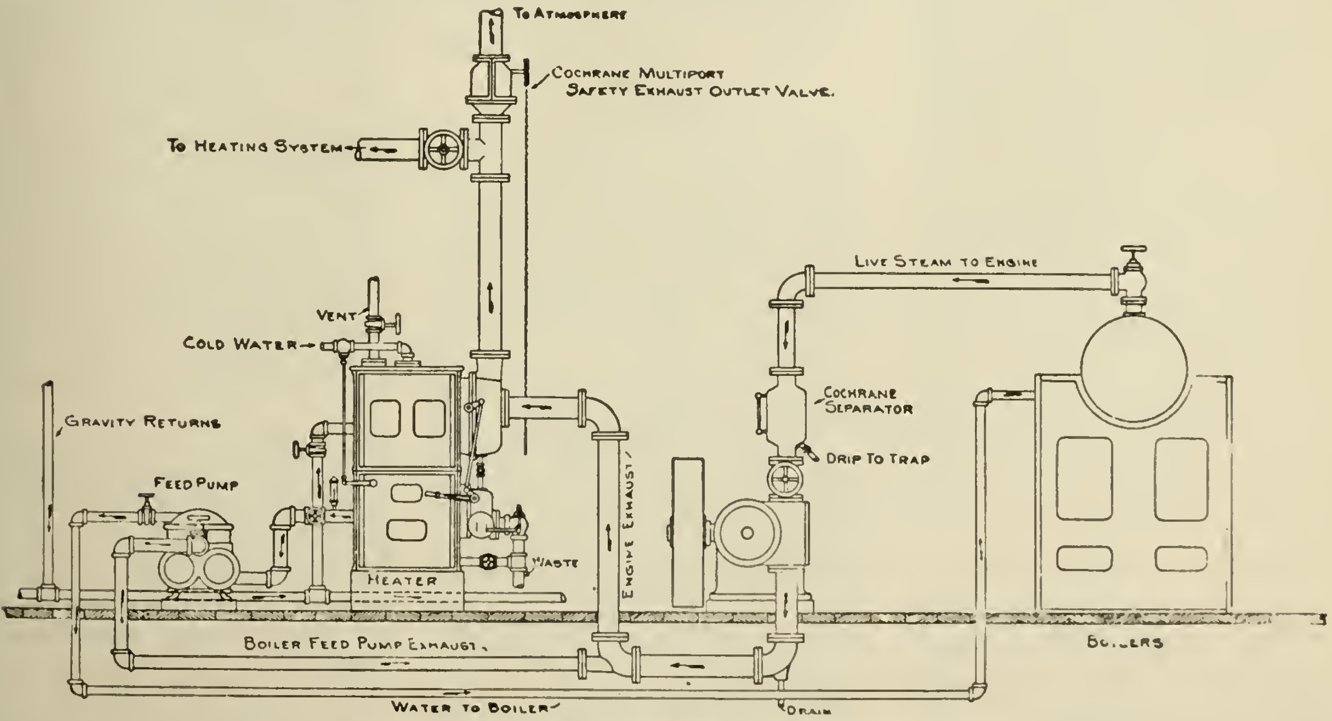

Fig. 6—Heating System Utilizing Exhaust Steam From Engine.

of a hand screw. About seven years later, the first fuel overfeed inclined grate stoker was patented by Hall. In this arrangement the grates were inclined, having reciprocating grate bars upon which the fuel was pushed. In 1876 the first underfeed multiple retort stoker was brought out by Smith. This was probably the first underfeed stoker to be used commercially, but it was only on the market a short time when it went into disuse. The illustration in Fig. 5 is a Frederick stoker and probably one of the latest stokers of this type to be brought out.

We have only given the dates when stokers of a certain class were first brought out, as a guide to indicate the development and advancement made upon these lines. It is needless to say, that numerous other stokers have been placed on the market since the introduction of those mentioned, and we think that there should be little or no difficulty experienced by anyone wishing to select a suitable stoker from the large assortment there are on the market, to meet with any requirement his plant demands.

Utilizing Exhaust Steam

There are various ways of utilizing the heat from the exhaust steam of an engine, one of the most common of which is a feed water heater. Great economics can also be effected when the surplus of the exhaust steam, above the amount that is required for heating the boiler-feed water, is applied to heating buildings, drying materials, cooking or any other process for which low pressure steam is suitable. In Fig. 6 we give an illustration of this arrangement where the exhaust steam from the engine is thoroughly cleansed and purified through an open induction Cochrane feed water heater. The steam is here separated from any oil, so that the returns of condensate can be brought back to the heater and used over again as feed for the boiler. The heater then serves as a receiver or return tank for the condensate, at the same time admitting the necessary amount of raw water to make up the total boiler-feed supply. If there is not sufficient exhaust steam both to heat the feed water and to meet the demands of the heating system, the exhaust steam can be supplemented automatically by live steam through a reducing valve set at a pressure somewhat lower than that for which the back pressure valve is set, so that the reducing valve will operate only when the supply of exhaust steam is deficient. Fig. 7 illustrates the form of heater used in this system.

The Present Day Boiler Room

When we come to survey the up-to-date boiler room and compare the lot of the engineer in charge, with that of 50 years ago, we think it will be admitted the engineer of the present day has the much more enviable position.

In many of the better laid out plants the process is almost automatic, and the heavy manual work that at one time was so closely associated with a boiler room, is reduced to a minimum. When we look at the stokers, automatic feed regulators, soot-blowers, ash conveyors and the numerous other up-to-date appliances in a boiler room, we quite realize we are aiming at increased efficiency and greater economy by introducing these appliances, but it must be admitted by the engineer, that these methods greatly decrease the drudgery work of the boiler room and tend to make the process about the boilers a much more interesting one by the absence of the heavy and unpleasant duties that once had to be performed.

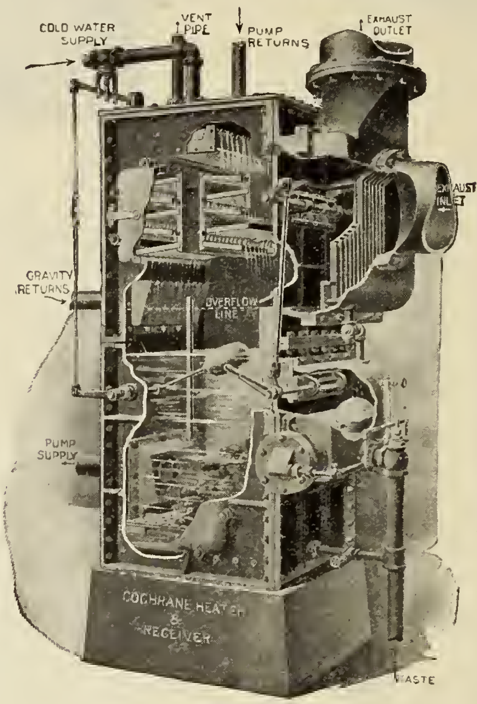

Fig. 7—Open Inudction Feed-water heater.

EXPLODED AND KILLED AT 300 POUNDS

By W. F. S.

The following interesting news item appeared in a recent issue of a North Dakota newspaper:

"In a threshing machine explosion that tore the steam engine to fragments scattering heavy parts sixty rods from where the machine stood, Gunder and Lars Larson, brothers, age 35 and 39 years, were instantly killed and five other workmen injured.

"The accident ocurred yesterday afternoon at the Vaagen farm five miles from Carpio. A defective safety valve which failed to operate when a pressure of 300 pounds of steam was generated is blamed for the tragedy. The victims were blown to pieces, fragments of their bodies being picked up a hundred yards from where the engine stood."

Sounds somewhat as though they were testing the safety valve with a boiler full of live steam at 300 pounds pressure, doesn't it?

If this news item is true it simply proves the writer's contention that most boiler explosions are preventable.

DEVELOPMENT OF THALE OIL

(Continued from page 24)

ammonium sulphate. The gas and naphtha, after being thus freed from ammonia, are then scrubbed in another tower by means of oil spray, which removes the naphtha and other condensible products—the emerging gas being used as fuel, while the oil is subjected to refining. The crude oil that is driven off from the shale is shipped to a refinery, where it receives the same treatment that is given to the crude oil that is obtained from the wells.

Among the more important products (in addition to oil) obtained from the retorting of shale, are ammonium sulphate and fertilizer, as we have already stated. The ammonium-sulphate content of American shales is not so high as in Scotch shales, but it averages about 10 pounds of sulphate per ton of shale, unless special retorts are made for realizing a higher ammonium-sulphate recovery, at the expense of the oil yield. The spent shale is in good demand as fertilizer if it is produced in the vicinity of agricultural land, but it cannot profitably be shipped to any great distance. Analysis indicates that the shale contains nitrates up to 6 per cent., together with small amounts of potash and phosphoric acid. This showing, alone, would hardly entitle it to be classed among the desirable fertilizers, but it apparently acts mechanically as well as chemically—possibly facilitating the aeration of the soil, and perhaps absorbing moisture from the air, to be drawn on by the plant-roots. It is possible to recover many other by-products, similar to those obtained during the process of well-oil refining; but a great deal of study and experiment are necessary before such products can be produced in quantities sufficient to make the work commercially profitable.

The hazards that we shall encounter in connection with this new industry may be forecast with a fair degree of accuracy from the knowledge and experience that we have already had in connection with steam-shovel operations, quarrying, coal mining, the destructive distillation of coal, and oil refining. Having such a foundation, it should be possible to enter into the development of the new industry with confidence that it will be quite practicable to assure safer working conditions than those that usually prevail in connection with pioneer work of other kinds.—Steam.

China, for the most part, is lacking in refrigerating facilities, and, because of this, vast quantities of salt are required for preserving food. The per capita consumption of salt in China averages twelve pounds annually, exclusive of salt used for manufacturing purposes. Crude salt is obtained from sea water along the entire coast line, from brine wells in the extreme western Province of Szechwan, and from the salt lakes in Mongolia. Some rock salt is also taken from the salt mines of Yunnan in the southwest.

Practical Application of Refrigeration

A Brief Outline of the Salient Features and Physical Laws That Underlie the Design of Refrigerating Systems

By FRED OPHULS*

THE number of industries in which refrigeration is a part of the manufacturing process is growing from year to year. It is gratifying that improvements in the application of refrigeration are keeping step with the growth of the refrigeration industry.

Since it is impossible in a short talk to cover the whole subject in great detail it may interest you to have me give you a brief outline of the most salient features and physical laws that underlie the design of refrigeration systems and the application of refrigeration in the arts to-day.

The usefulness of volatile liquids for producing refrigeration was discovered many years ago, still we are learning more every day about their correct use for this purpose. It is this knowledge that should be broadcasted more generally so that everyone who operates refrigeration systems and those who supervise such operation can do so intelligently.

If I make the bold statement that even to-day in nine out of ten plants, where refrigeration is used, the refrigerant is not handled so as to obtain the best possible results both as regards output and economy of operation, you would be inclined to accuse me of gross exaggeration. Since I inspect and analyze plants in most every part of our country, and I have found this to be the case, I have the right to make this broad statement. It is, therefore, not amiss to touch briefly on the fundamental principles that underlie the use of volatile liquids for producing refrigeration.

Use of Refrigerants

All these liquids have the same general physical properties like water. They boil away or condense at a finer temperature for every pressure to which they are subjected. When they boil away they absorb heat and when they condense they reject heat. While water at atmospheric pressure boils at 212 degrees F. liquid anhydrous ammonia boils at this pressure at about 28 degrees F. This is the property that makes anhydrous ammonia useful for refrigeration purposes.

It is, therefore the liquid ammonia that it injected into the low pressure side of the system that produces, in boiling away into ammonia vapor, the actual refrigerating work.

This brings us to one of the most important errors made in the handling of refrigeration systems.

Insufficient Ammonia in the System

What will happen when the supply of liquid ammonia in the system is insufficient—three things can happen:

First, when the expansion valves are open so far that the liquid supply in the receiver drops to the liquid outlet, high pressure ammonia vapor passes with the liquid ammonia to the low pressure side. The refrigerating effect of every pound of vapor that passes through the expansion valves with the liquid has less than one-eight hundredth the refrigerating effect that a pound of liquid has and is, therefore, of little help in producing the refrigeration required.

Second, the pound of vapor after it is reduced to the suction pressure on passing through the expansion valve will have the same volume, that is, it will occupy the same space in the low pressure system as the one pound of liquid ammonia, when it has been vaporized by the heat it has absorbed and has produced more than 800 times the refrigerating effect than the one pound of vapor that come into the low pressure side with it.

Third, the refrigerating machine, of whatever type it may be, compression or absorption, has a definite pumping capacity. If it has to handle ammonia vapor produced by the boiling away of liquid in the low pressure system it is helping to produce the largest amount of refrigeration that it is capable of. If, on the other hand, the machine has to handle in addition to each pound of vapor produced by the liquid, one pound of vapor that passes with it through the expansion valve, it must either be operated at twice the speed to do its work or else at the same speed can do only about one-half of the work.

Using Too Much Power

Furthermore, it takes just as much power to compress a pound of vapor from the suction pressure to the condenser pressure, whether or not this pound of vapor has come through the expansion valve or has been formed by evaporating a pound of liquid in the low pressure side. Therefore, in the case above stated twice the power will be used to develop a ton of refrigeration that should be.

The remedy is to have a gauge glass on the liquid receiver and keep the liquid level in the receiver at least six or more inches above the liquid outlet.

On the other hand, the operator may be aware of the foregoing and maintain the liquid level in the receiver and yet the output or the efficiency of the system fall far short of the result that should be obtained.

This condition of the plant can be illustrated in a few words. Supposing a plant is called on to develop one hundred tons of refrigeration and the refrigerating machinery is properly proportioned to do this work. Roughly speaking, about one-half of a pound of liquid ammonia must pass through the expansion valve per minute per ton of refrigeration. For one hundred tons, about fifty pounds of liquid per minute is required.

Insufficient Ammonia in the System

If there is not sufficient anhydrous ammonia in the system, and still the operator tries to maintain a proper liquid level in the receiver he must pinch down the expansion valve so that less than the fifty pounds of liquid passes through it per minute. The result is that the one hundred tons of refrigeration cannot be obtained. Mostly before charging more ammonia the operator speeds up the machines, pulls down the suction pressure and tries to make up the difference in that way. He can sometimes on a large system secure the necessary refrigeration in that way, for it is a fact that the lower the suction pressure for any given temperature in the refrigerating system the smaller will be the amount of liquid that can be held in the low pressure side. The speeding up of the refrigerating machines with a consequent drop in suction pressure will, therefore, cause a quicker evaporation of the liquid on the low pressure side and the liquid receiver will start to fill and the expansion valve can then be opened to let fifty pounds of liquid enter the low pressure side every minute.

Operating at a lower back or suction pressure than is necessary to produce the result means excessive power use.

It is easy to illustrate why a certain refrigerating system may hold more or less liquid ammonia when doing the same amount of useful work.

Take, for instance, a standard can ice making system. Suppose that it contains a sufficient number of ice cans so that the desired output can be harvested with an average brine temperature of 16 degrees F. As long as this brine temperature can be maintained so long can the usual ice harvest be continued. For proper economical results the plant should be equipped with a brine cooling system so that this brine temperature can be maintained with liquid ammonia boiling in the system at from 9 to 10 degrees F. In this case the temperature difference between the brine and liquid ammonia boiling in the cooling system is only from 6 to 7 degrees F., a small but correct temperature difference. Naturally the liquid ammonia boils slowly and a large amount of liquid ammonia must be held in the brine cooling system so that results are obtained. As an extreme case, let us suppose that the ammonia charge in the system is not sufficient to keep all the liquid in the brine cooling system that is required to produce the temperature difference of from 6 to 7 degrees F. and still have enough liquid in the receiver to seal the liquid outlet. The ice making capacity can be maintained provided the refrigerating machines are large enough, by dropping the suction pressure. Say we can drop the suction pressure so that the liquid boils at 0 degrees F. There is now a temperature difference of 14 degrees F. between the brine and the ammonia. Boiling will go on twice as actively as it did before. Under this condition a lesser amount of liquid ammonia will be required in the brine cooling system and, therefore, more is available to properly fill the receiver.

It is needless to point out to you that more power is needed to do the refrigerating work at a low than a high suction pressure.

An ample supply of ammonia in a refrigeration system and maintaining the proper liquid level in the receiver is, therefore, of prime importance in all refrigeration systems, whether they are used for distilled or raw water ice-making, for cold storage work, for water cooling or for any of the many purposes for which refrigeration is used to-day.

Danger from Slugs of Liquid

A refrigerating system may be so designed that it is dangerous to try and fill the low pressure side with as much liquid ammonia as it should hold to obtain best results. For instance, in ice making plants the harvesting of ice in all parts of the freezing tanks, and replacing the cans filled with water, has a varying effect on the action of the liquid ammonia evaporating in the brine cooling system. When harvesting ice at the end of the tank where the expansion valves are located, heat is added more quickly to the brine than in other parts of the tank, causing more rapid evaporation of liquid at this point. The rapid production of vapor at this point may push the liquid forward in the rest of the system more rapidly than when the ice is harvested at the other end of the tank with the result that slugs of liquid will be pushed out of the cooling system and if proper means are not available to separate this liquid from the vapor before the latter gets to the refrigerating machines, liquid hammer in the machines may appear, resulting sometimes in rupture and serious accident.

In well equipped refrigerating systems means are always provided to avoid this danger. I might point out here that the usual accumulator system now in common use will eliminate the danger.

Having outlined briefly how the refrigerating fluid must be handled to obtain both output and efficiency, it might be of interest to analyze in the same manner other parts of the refrigeration systems and tell briefly the way one can determine the extent to which one can go to equip a refrigeration plant, for whatever purpose it is used, to obtain maximum economy, and, what is more important, the largest returns on the investment.

Keeping Plants Up-to-Date

It is remarkable how many ice making and refrigerating plants there are from the operation of which the owners desire a good return on their investment and still if the machinery equipment of these plants was added to, here and there, and some of the obsolete machinery replaced by more modern apparatus the results would be most gratifying. To safeguard the investments in these plants it is absolutely necessary to keep the machinery equipment up-to-date. How often does it happen that the owners of these plants are threatened with the entire loss of their investment by the ruinous competition from a new and more modern plant. There are two safe ways to avoid this dilemma. The one is to keep the plant up-to-date and the other is to set up an ample reserve for depreciation and obsolescence with which the cost of these improvements can be met. It is not enough that such a reserve is set up as an item of bookkeeping but the actual cash must be set aside and invested in safe securities so that it is available when needed.

Choice of Proper Machinery

When building a new plant the choice of the proper machinery equipment is very important but difficult for the business man.

Taking for example ice making plants, in which most of you are interested, shall the plant be equipped with ten, twelve or more cans per ton? Up to a certain maximum number, the more cans per ton used the less will be the power to operate the plant per ton.

When the available water supply is so poor that a distilled water plant must be installed the choice of the equipment must be such that just enough distilled water is available to fill the can. When evaporators are used to make up some of the distilled water the problem is the same as that for a raw water plant.

When the water supply is of such a quality that raw water ice can be made either direct or after proper treatment, it is necessary to get bids on the various types of apparatus available with freezing systems, based on say twelve to eighteen cans per ton, and to figure up closely the cost of the completed plant in each instance. After that the probable cost of ice for these various systems must be determined. The cost of ice in each case must include every item of expense, labor, fuel or purchased power, waste and oil, sundry expenses. repair and upkeep, labor and materials, ammonia and salt or calcium chloride, taxes, insurance, depreciation, administration expenses, handling labor, etc.

This information, taken together with the reliability of the apparatus proposed in each case gives the answer to the problem. That plant which nets the largest income on the total investment is the one that must be chosen unless financial considerations make another choice desirable.

A brief summary of the most modern machinery for refrigeration systems may be of assistance to you. Starting with the compressor—the purpose of this machine is to remove the ammonia vapor from the low pressure side and discharge it into the high pressure or condensing side. That machine which obtains this result with the least expenditure of power and which performs this function in the most reliable and safe manner is the one to be chosen.

In some parts of this country the slow speed machine turning over at from 60 to 90 r.p.m. is preferred. In other parts medium high speed machines are almost always installed; these machines running at from 120 to 200 r.p.m. What is actually the difference between these machines, assuming that both types are properly designed? Will a slow speed machine last longer than a medium speed machine? The correct answer to these questions is that there is no difference between them, considering the service they will render and the length of life. The pressures on the moving parts are the same. It is true that the moving parts of the medium speed machines are lighter than those of a slow speed machine. This is a distinct point in favor of the former. Repair parts cost less to buy and install. They occupy less space. The piston speed is the same. Take for instance a 36-inch stroke slow speed machine running 75 r.p.m.—the average piston speed is about 450 feet per minute. The equivalent medium speed machine has a stroke of 15 inches and operates at about 165 r.p.m., or an average piston speed of 413 feet per minute.

The failure of some of the high speed machines has been due to faulty design, which has since been remedied. The most important feature of a compressor, next to the safe design of all its parts, is the effective valve area of its suction and discharge valves. If the valves are of such size and the required number is used that the vapor speed through them does not exceed from 3,000 to 5,000 feet per minute, the medium speed machines so equipped are far superior to most of the slow speed machines now on the market.

Ammonia Condenser

The ammonia condenser is going to be entirely different apparatus from the atmospheric or double pipe condensers now most commonly used. A flooded condenser is an abortion. Its design is contrary to all the physical laws governing the condensation of vapor.

Would a steam engineer ever think of using our open air or double pipe condensing steam? No. Why should we? The fact is that modern refrigerating plants are now being equipped with shell and tube condensers that are assuming more and more the form of modern steam condensers. This new type takes up less space, is easier to clean, requires less surface and gives better results, that is, lower condenser pressures, than the old types. Heat transfer co-efficients

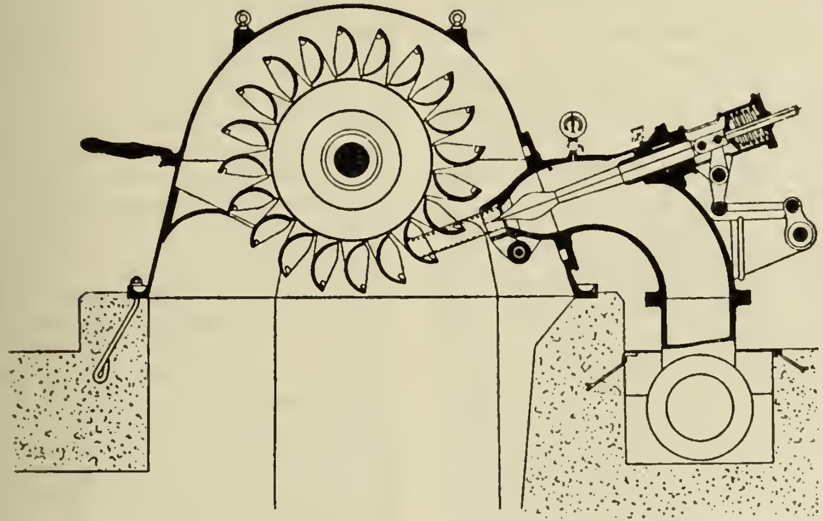
Pelton Water Turbines

Turbine Fitted for 24-Hour Service for Driving Air Fan at Colliery

THE utilization of the water power made available by mining operations is more often discussed than practised, but the high cost of fuel, especially in many of the metalliferous mining districts, has given the subject a more practical turn. For auxiliary power supply in mines the water turbine utilizing the head of water developed by shaft sinking and the driving of winzes or inclines is of great value, and deserves more consideration than it has yet received. An interesting example of the harnessing of mine water is provided by the Pelton turbine supplied recently by Messrs. Salterns, Ltd., for the driving of a Keith induced draught fan at the Argoed Colliery in South Wales.

The fan shaft is in the centre of the turbine house, and on one side is the electric motor, and on the opposite side the Pelton wheel, and normally the fan is driven by the Pelton wheel, which is designed for 24 hours' service, and in emergency the electric motor could be used.



Pelton Water Turbine.

The Pelton turbine is normally of 5 b. h. p. running at 500 revs. The head of water in this instance was only 110 ft., but as it was essential to have a turbine which was absolutely fool proof, it was decided to use this type of wheel in preference to a Francis turbine. The inlet connection on the Pelton wheel was 6 in. diameter.

These standard Pelton wheels are of very robust construction, and are totally enclosed in accurately machined cast iron houses, furnished with bronze lined ring oiling bearings. They are also furnished with ball bearings if required. The buckets are accurately machined and fitted on a tight press fitted on a solid disc runner, which is turned all over, and balanced; turned and ground steel bolts of 60 ton tensile strain are tightly pressed into reamered holes. The turbines are fitted with a bronze needle and a bronze nozzle for hand regulation, and a hand hole with a cover plate is fitted for access to the nozzle if required.

Standard sizes of this pattern are made suitable for any head of water up to 500 ft., but special Pelton wheels, which have the top part of the case made removable, have been designed for heads of water up to 2,000 ft. or more, and single units of 1,600 h. p. have been supplied.

The Pelton turbine is constructed in forms suitable for either hand regulation or fitted with a deflector and patent universal oil pressure governor, which includes the oil pump, servo-motor, and double compensating gear. The pendulum shaft is fitted with ball and thrust bearings, and the drive shaft with bronze and steel silent skew gear running in oil. The regulating needle is mounted on a very stiff steel shaft, and is well supported and protrudes into the water-way with a minimum of obstruction. The needle shaft is furnished with substantial bronze liners, and fitted with a water-tight gland.

By means of the levers and links shown in Fig. 1 the movement of the needle or deflector is automatically controlled from the governor, and it will be noticed that a coil spring in compression is fitted, which thrusts the needle in towards the nozzle, thus reducing the amount of energy required from the governor to a minimum.

The action of the patent governor is as follows:—A deflector is fitted which cuts in to the jet from above, the aperture in the deflecting plate being given a circular shape so that it almost embraces the jet.

One Servo-motor piston is connected to the deflector, so that immediately there is any increase of speed the deflector cuts into the jet and throws a portion of the water away from the wheel. The needle is then allowed to travel slowly forward so as to economise the water and prevent any possible shock on the pipe line. An interesting feature is that it is only necessary for the deflector to move half way into the jet to deflect the whole of the stream.

After the needle has moved forward and the jet is reduced in diameter to suit the new conditions it will be found that the deflector is resting just clear of the reduced jet ready to go into instant operation again in the event of the load being further reduced.

It will be noticed in Fig. 1 that at the back of the housing a "silencer" or baffle plate is fitted to prevent waste water being carried up into the top of the housing and again falling on the wheel. In the larger Pelton turbines a rotary oil pump is included, fitted with a filter and a cooling pipe placed in the exhaust water so that a continuous supply of cooled oil is admitted into the top of the bearings. The inlet pipe can be bolted on at any angle as convenient. The turbines are usually furnished with a pressure gauge and Tachometer. Messrs. Salterns, Ltd., also manufacture Francis turbines and complete hydro-electric equipment.

PRACTICAL APPLICATION OF REFRIGERATION

(Continued from page 30)

of 150 B. t. u. are now the rule rather than the exception.

Another innovation is the compound compressor. Some think that this compressor is only desirable for low temperature work. This is not so. They should be used for ice making as well. Whenever the ratio of compression, that is the absolute condenser pressure divided by the absolute suction pressure, is four or more, compound compressors should be used.

Please remember that the above are not views based on a whim of the moment. Every statement I make is borne out by actual and accurate tests made on the machines and apparatus discussed.

---

*Paper read before Southwestern Ice Manufacturing Association at Fort Worth.

Twenty-four thousand tons of freight had to be transported fifty miles into a veritable wilderness in connection with the construction of the Gouin dam on the St. Maurice river. According to Major Brace, M. E. I. C., the greater portion of this had to be transported up-stream for thirty miles and then transferred to standard gauge railways built for the purpose. Comfortable quarters had also to be built for the workmen, and to avoid danger from fire, oil-burning locomotives had to be used.

Impulse Turbine Versus Reaction Turbine

Comparative Merits and Efficiencies of Various Types of Turbines Under High Heads, Giving an Analyses of Results and Pointing Out Mechanical Drawbacks Under Heavy Pressures

ALTHOUGH the impulse wheel is typically a high head unit using comparatively little water as compared with the reaction wheel which is a low head unit often using vast quantities of water, there are many factors which enter into a consideration of the choice between the two types of hydraulic prime mover, particularly for fairly high heads. In the following discussion the term "impulse wheel" is considered as restricted to the "Pelton" wheel, while as reaction turbines are now for the most part of the Francis type, especially when operating under high heads, the choice of impluse or reaction turbine virtually resolves itself into a choice between a Pelton and a high head Francis. The primary criterion for choosing between the two types is the specific speed formula.

$$N_s = \frac{\text{r.p.m.} \times \sqrt{\text{H P}}}{H^{\frac{3}{4}}}$$

Where H is expressed in feet, values of N_s below 9 call for an impulse wheel, values above 11 for a reaction turbine, while between 9 and 11 fall within a debatable zone where other considerations usually determine the choice.

Theoretically, considering the specific speed formula alone, there is no limit to the head suitable for reaction turbines. Practically the revolutions per minute are limited by generator speeds, while horse-power is limited by quantity of water available. The higher heads can only be developed on mountain streams, which are usually of small volume. Even when a large volume of water is available at a high head, there are various mechanical difficulties in the design of a reaction turbine to fit the conditions. For instance, a casing large enough for the required volume of water must be of considerable thickness to withstand the heavy working pressure. This not only adds to the cost but a point is soon reached where it is difficult, if not impossible, to obtain sound steel castings of the requisite thickness and diameter. At the present time the highest head reaction turbines are those at the No. 3 plant of the Kern River development, Southern California. These were built by the Pelton Wheel Company and are of 25,000 h.p., and operate under an average head of 810 ft., and are of a particularly interesting design due to the peculiar operating conditions which call for different speeds for different electrical conditions at alternate seasons of the year, necessitating arrangements being made for changing the runners at short notice without disturbing the remainder of the apparatus. As a matter of fact, reaction turbines have been considered and even designed for heads of as much as 1,100 ft., but so far nothing of this kind has been built.

As regards impulse turbines the highest head with which it has as yet been attempted is 5,320 ft., and there are four 3,000-h.p. units of the Pelton type operating under this head at Fully, Switzerland. This plant, like the Kern River plant, called for special arrangements in the shape of protective devices in case of pipe bursts or governor failures. Opportunities for development of such high heads are of course rare, at the present time few plants are working on heads higher than 2,000 ft., in fact it is often the better proposition to break up these high heads into two or more stages, as for instance, the Big Creek development in California with a total head of 6,000 ft., which will, when complete, be divided into five sections.

In the case of an impulse wheel, the head determines the spouting velocity from the formula $v = \sqrt{2gh}$. Given the water quantity and spouting velocity, the jet diameter is determined. This more or less fixes the wheel diameter, because, although special types of construction permit the use of a low ratio of runner diameter to jet diameter, an increase of the latter usually means an increase of the former. Therefore, if all the conditions of a project are kept constant except the horse-power output, the weight of an impulse wheel installation will increase more rapidly with increase in power turbine. Consequently, when any given set of hydraulic conditions except the power output is kept constant, a point is reached, with increase of power output, where the cost of an impulse wheel installation exceeds the cost of a reaction wheel installation, although this would not seem to be readily apparent when the extreme simplicity of the impulse wheel is considered. Just where this point is in any given case cannot be determined in advance of a study of the conditions.

When, however, this point lies within the debatable zone, as determined by the specific speed formula, the question of cost may be so important as to be the determining factor. The specific speed for any given project may be varied considerably by varying the revolutions per minute or the capacity of the individual unit. The former course is occasionally adopted where a trial solution of the specific speed formula indicates a different type of unit than the one favored by the other conditions, but it must be remembered that variation in revolutions per minute is limited by the range in generator speeds allowed by the electrical manufacturers.

For most large projects the maximum efficiency of a well-designed impulse wheel will lie between 84 per cent. and 88 per cent., while a similar reaction turbine would show better results by about 4 per cent. On the other hand, the impulse wheel will have a flatter efficiency curve. Consequently, when a plant must operate for a considerable part of the time on fractional loads, the average efficiency for an impulse wheel installation is likely to be higher than that of the corresponding reaction turbine, even if the maximum efficiency of the latter is higher. At the same time it must be borne in mind that the efficiency of the reaction turbine depends upon the maintenance of minimum clearances between the runner and other parts of the turbine. Corrosion and erosion may so reduce these clearances as to eventually call for renewal of runner and other costly parts. On the other hand these bad effects of the water are not so marked with the impulse wheel, and in any case renewal of the worn parts is a simpler and cheaper matter. In fact, for this reason alone, a new development in Arizona operating on a comparatively low head of 110 ft. with a maximum quantity of water of 720 cub. ft. per second, incorporates impulse turbines of 1,000 h.p. each, although the conditions of head and quantity would appear to be the reverse of favorable. It so happens that the water is very corrosive, and being also used for irrigation is heavily charged with silt at certain periods of the year, while the requirements of the irrigation scheme render the water quantity very variable. Hence the choice of the impulse wheels which in this instance have vertical shafts and six nozzles, the number of which actually in service is varied according to the quantity of water available so that the efficiency curve is practically flat whatever the quantity of water.

It should be mentioned, of course, that water used for irrigation should not be robbed of its silt, in consequence settling basins are often inconvenient under such conditions, but the water supplied to the Kern River plant previously referred to is settled before passing through the turbines, and although most of the deposit is fine enough to pass a 200-mesh sieve, it would, if allowed to remain in the water, do considerable damage in view of the head and the fact that the turbines are of the reaction type.

In such cases the silt should be removed as far as possible in settling basins, but even then there is the risk of erosion if the water is initially charged

Air Pressure in Furnaces of Forced Draft Boilers

The Opinion of Engineers and Operators Relative to Methods of Obtaining Constant Low Draft—Same Principle Applicable to All Types of Fuel—Early Mechanical Regulators Cause of Bad Experiences

By E. M. ELIOT

AT THE well-managed power plant of a certain packing firm, the flue gases from one boiler showed CO_2 content of 10% with the draft controlled by a hand-regulated damper. After the installation of an automatic regulator for maintaining a low draft over the fire the CO_2 was increased by two to three per cent.

The boiler on which the experiment was made was a 700 H. P. Stirling Boiler, operating 12 hours per day, 300 days in a year. A good grade of Middle West coal was used, at $3.80 per ton, and a check of the boiler efficiency previously made indicated that a boiler horse-power could be produced with about four pounds of coal. The boiler was run approximately at rating.

Figure 1 shows certain curves which were available for the coal being used. (If the coal used had been an average Eastern grade, chart No. 2 would have been used instead of chart No. 1). The flue gas temperature, where the 10% CO_2 was obtained in the packing plant, was 550° F. and with automatic regulation of the draft was 480° F., this having been obtained by actual measurement. The combustible in the ash was 25%.

Entering the chart, Figure 1, at 10% CO_2 and projecting upward to the excess air curve, it was found that at 550° flue gas temperature, there was 80% excess air, and a boiler efficiency of 75.8%; also entering the chart at 12% CO_2, and projecting upward to the excess air curve, it was found that at 480° flue gas temperature, there was 52% excess air, and a boiler efficiency of 79.6%. Reducing these two efficiency figures for the combustible in the ash, they become respectively 69.8% and 73.6%.

$\frac{73.6\%-69.8\%}{69.8\%} = 5.45\%$ increase in boiler efficiency or saving in fuel.

The amount of coal used at 100% rating was

$\frac{700\text{x}12\text{x}300\text{x}4}{2000} = 5{,}040$ tons per year which, at $3.80 per ton, was worth $19,152.

Applying the fuel saving of 5.45% to the value of the coal—

$19,152x5.45% = $1043.80 saving per year.

As this was more than three times what it had cost to secure a low constant draft over the fire, the engineers were well pleased. The above figures are computed on a yearly basis.

Various objections to the use and value of low constant draft over the fire are urged from time to time, and are of interest not only in themselves, but as indicating the need for clearer thinking on this matter, if best results are to be obtained in the boiler room. At the risk of repeating some points already mentioned, these are listed together below.

1. Operators confuse boiler efficiency with furnace efficiency. They point to a satisfactory overall boiler efficiency, obtained by a boiler test, and say that they do not believe it can be improved, notwithstanding the fact that the percentage of CO_2 in the flue gases may be 8% or 9%.

Overall boiler efficiency depends on a number of factors, such as cleanliness of tubes, ratio of tube surface to grate area, amount of gases passing through the boiler, etc., as well as on the amount of excess air and temperature of gases. The draft over the fire affects the last two quantities, and if excess air can be reduced, and temperature of gases increased, (i.e. flue gas temperature reduced) without increasing losses elsewhere greater economy of fuel will result whether or not other losses in the boiler are eliminated. As a matter of fact, no other loss is increased by a measurable amount because of carrying a low draft over the fire.

The percentage CO_2 is the proper criterion upon which to base judgment concerning excess air and draft. If this is increased by any change, it is certain that a saving in fuel has been effected, (always excepting the extreme case where CO begins to be formed, whether the result can be detected by a boiler test or not.) It is possible that some other loss will increase enough to entirely wipe out the increased efficiency, due to better combustion conditions, but this is an argument for reducing such loss to its original amount. It does not in any way reduce the advantage of getting a high percentage CO_2 in the flue gases nor reduce the financial saving effected thereby.

2. Operators advance the argument that a high velocity of gases through the boiler is desirable especially to give a scrubbing action, which tends to clean soot from the tubes. They claim that low draft over the fire reduces the velocity of the gases.

It has been pointed out that draft does not appreciably influence the velocity of the gases in the boiler, except by changing the amount of excess air. When excess air is reduced, velocity is decreased, but this is a desirable condition under ordinary circumstances.

3. The statement is sometimes made that high draft is wanted at overloads, but whether manual or mechanical means are used for handling the damper, or induced draft fan, it is a very simple matter to change the adjustment to a higher constant draft when overloads are expected, and to put it back when the overloads have gone by. Such over-loads ordinarily last over an hour and can easily be anticipated. The draft

More Economical Method for the Burning of Gas

Correct Amount of Oxygen Essential—Liquid Fuels Require Less Excess Air Than Solid Fuels—Maintaining Control of Air-Combustion Ratio—Difficulties of Some Systems

WHEN gas was cheap and abundant, little thought was given to its economical consumption, but at present, with gas-making fuels becoming relatively scarce and expensive, more attention is being given to methods for utilizing all the available heat units in the gas. This article outlines briefly the various methods now in use, with their advantages and disadvantages.

The Air Supply

To burn a fuel efficiently only the correct amount of oxygen required should be supplied—no more, no less. When the correct amount of air is used and combustion is complete, the waste gases leaving the heating chamber consist only of carbon dioxide, water vapor, and the nitrogen present in the air supplied to burn the fuel. If sufficient air is supplied, some of the combustibles in the form of carbon monoxide or other incompletely consumed carbon compounds pass out of the furnace, thus wasting part of the fuel. If an excess of air is present, a large part of the heat liberated is wasted in heating this excess air to the temperature of the furnace.

Utilization of Heat

All fuels cannot be burned in a given heating system with the same efficiency. These differences are due to the physical properties of the fuels themselves. To obtain efficient heat utilization, combustion must not only be complete, but also rapid to produce an intense "reaction temperature," resulting in the greatest possible heat gradient and the best heat transfer, for heat will flow only from points of high temperature to points of lower temperature. The greater the temperature difference, the more heat utilized.

To obtain maximum temperature in the combustion zone, not only should the correct amount of air be supplied, but the air must come in intimate contact with the minute particles of the combustible; and the resulting products of combustion rapidly replaced by a fresh supply of air. If this is not the case, combustion will be slow, and the "reaction temperature" and temperature within the furnace low. This is well illustrated by the covering up and smothering of a fire, where the products of combustion are retained, with a fresh supply of oxygen excluded, eventually causing the fire to go out.

Application of Liquid Fuels

In the application of liquid fuels for industrial heat generation, the oils or tars are sprayed into the combustion chamber, thus breaking it up into a large number of minute globules, and exposing large surfaces. When the molecules on the surface of the globules come in contact with the molecules of oxygen present in the air supplied, at the proper temperature, combustion takes place and heat is liberated. This generation of heat causes a further breaking up of the small globules, to form gas molecules, exposing new surfaces capable of being oxidized as soon as the atmosphere at the surface is replaced by a fresh supply of air. This step in the direct burning of oil requires time, and to speed up the reaction and insure complete combustion before the gases generated and products of combustion leave the heating zone, excess air is needed.

However, liquid fuels require less excess air than do solid fuels, due to the fact that larger surfaces are exposed and combustion is therefore more rapid. Normally not over 25 per cent. to 50 per cent. excess is required, but in average practice it is from 50 per cent. to 100 per cent. This is due to the lack of development of suitable combustion apparatus that will automatically maintain a constant air-combustible ratio at varying consumptions. As less excess air is required for the combustion of liquid fuels, the "reaction temperature" and the temperature within the combustion chamber is hotter. or more intense.

Amount of Heat Obtainable

The amount of heat utilizable from any fuel depends upon the temperature at which the waste gases leave the effective heating zone, as well as the amount of excess air used. The higher the waste gases, including the excess air, are heated, the more heat they absorb from the furnace. If the gases leave the heating chamber at a relatively low temperature they carry out but little heat, even though excess air be present. But in not every heating system is it possible to discharge the products of combustion at a low temperature, and large heat losses necessarily occur. Heat losses that occur through lack of control of excess air for solid and liquid fuel combustion run into millions of dollars each year.

Using Gas for Fuel

Gas is the ideal fuel. Its physical properties are such that excess air is not required for its efficient utilization in modern appliances, or gas burning systems. The molecules comprising gas are neither large nor compact; when mixed with air, rapid, complete combustion takes place, due to the intimacy of the mixture and the large exposed surface of the molecules of the combustible. Maximum temperature is thus obtained, permitting the greatest heat transfer with minimum heat loss. In brief, it is the most efficient type of fuel known to-day.

Gas is the only fuel that can be applied to give a reducing, oxidizing or a neutral atmosphere in the furnace, that can be changed readily at will. Wherever there is lack of control of the air-combustible ratio, heat losses occur with gas as with other fuels. However, due to the physical characteristics of gas, no excess air is necessary for rapid and complete combustion. Herein lies its greatest advantage over other fuels, for due to this property alone, consumers obtain more effective work from an equivalent number of gross B. t. u.'s with gas than from any other type of fuel. It is, therefore, not logical to compare the cost of fuels on the basis of a "gross B. t. u." relationship. Relative fuel values depend upon the percentage of "gross B. t. u. as fired" that are "available" to do the work under the conditions the fuels must be burned. As gas can be fired with no excess air, no heat losses occur in the waste gases, as with solid and liquid fuels; consequently, a greater per cent. of the "gross B. t. u. as fired" are rendered "available" to do effective work.

Control of Air-Combustible Ratio

Only recent developments of modern gas combustion systems have made perfect control of the air-combustible ratio possible. They have brought about flexibility and efficient combustion, for without them there can be no control over combustion conditions and large heat losses in the waste gases occur.

For every volume of a given gas consumed there is a definite volume of air required for complete combustion. This definite ratio of gas to air must be maintained at all rates of consumption if the most efficient combustion is to result. The maintenance of this air-gas ratio is therefore fundamental to any efficient gas combustion system.

Absolute Control With Gas

With gas as a fuel it is possible to have absolute and automatic control of furnace conditions and temperature at all times, and with its rapidity and intense temperature of combustion, it saves time in bringing the furnaces up to temperature. The use of gas also eliminates spoilage and waste of material by improper control of combustion conditions and furnace temperatures. There are also no labor charges for handling the fuel, or for the removal of ashes. Gas is, therefore, the ideal fuel, but its position in fuel classifications is made possible only by a correctly designed gas combustion system.

Gas Combustion Systems

A large number of industrial gas combustion systems are on the market. Many are more or less effective and suitable for the burning of gas, some suitable only for special installations, and others do not obtain the correct results at all.

Practically all industrial gas systems consist of a compressor or blower to deliver the required volume of gas or air to the furnace; a pressure regulator to maintain a constant pressure and uniform flow of gas to the furnace under varying loads; and an air-gas ratio control device for maintaining the desired combustion conditions. This latter, the air-gas ratio control equipment, may be an integral part of the compressor system or may be some modification of the well-known Bunsen burner, in which the air is injected by the gas flowing through the burner, or a combination of both.

The Five Types of Systems

Five distinct types of gas combustion systems are in general use, which utilize some or all of the foregoing three principles. They are:

(a) The two pipe system, in which gas and all the air required for complete combustion are delivered to the furnace in separate pipes.

(b) The high pressure Bunsen system, in which the gas alone is delivered under high pressure to a modified Bunsen burner located near the furnace, the air required for complete combustion being induced at the burner.

(c) The central unit total premixture system, in which the gas and all the air are mixed at the compressor or blower and delivered to the furnace.

(d) The individual unit total premixture system, in which the gas and all the air are mixed by individual blowers located at the furnace and delivered to the burners through a short pipe.

(e) The partial premixture system, in which the gas and a portion of the air are mixed and delivered to a modified Bunsen burner located at the furnace, where the remaining air required for complete combustion is induced.

Difficulties of Some of the Systems

The objection to the two pipe system is that it is expensive to install. This system is sometimes called "the two valve system." Its advantage is that no Bunsen burners are needed, which in themselves have limitations, but it places the control of the atmosphere within the furnace in the operator's hands at all times, a control which can be made automatic if desired.

The high pressure Bunsen system is low in first cost, and has found a wide application. The main objection is that it is limited by the sole use of the Bunsen burner for the injection of air, which cannot be correct for changes in the density of the gas. If the gas density changes, as happens with all manufactured gas, there is no control of the ratio of air to gas, and waste of fuel results.

The central unit total premixture system has a disadvantage in that the compressor must be large and expensive, as it must handle all the gas and air required for complete combustion; and in that it delivers an explosive mixture to the furnace, which in itself is dangerous. Due to the fact that all air and gas must be handled in a single pipe, the pipe lines are large and costly. Pop valves must be installed to take care of explosions in the pipe line.

The individual unit total premixture system also has the disadvantage of handling an explosive mixture, but as the blower is usually installed close to the furnace, large volumes of air and gas are not in the pipes and the danger is much less. The pressures used on such systems are low and the power requirements correspondingly small. However, most of such systems lack the fundamental automatic air-gas ratio control at varying loads of gas consumption.

Partial Premixture System Most Efficient

The partial premixture system overcomes practically all disadvantages inherent with other systems. The installation is relatively small, as only a portion of the air is mixed with the gas and handled by the compressor—the remainder required for complete combustion is induced at a modified Bunsen burner located at the furnace. As a portion of the air is mixed with the gas at the compressor, only the small remaining portion required for complete combustion must be induced at the burner. Since only a portion of the air must be induced, less energy in the gas (partial premixture) stream is required at the burner, and the pressure required and power consumption are correspondingly low. As a result of premixing a portion of the air with the gas at the compressor, any variation in the density of the gas is neutralized automatically by the density of the air, which is constant. There are smaller fluctuations in the energy of the gas stream at the burner and the air induced remains more nearly constant than would air induced by the energy of a high pressure gas stream alone. Wide variations in the air-gas ratio are eliminated, and combustion conditions and the temperature within the furnace remain constant. Large heat losses in the waste gases are therefore minimized. The partial premixture system or Selas system, maintains this constant air-gas ratio irrespective of the amount of gas consumed and the variation in consumption.

This system also enables the operator to obtain a neutral, a reducing, or an oxidizing atmosphere within the furnace, as desired, and to maintain the same automatically.

Use of Gas Increasing

Since gas can be applied more efficiently than any other fuel, we find its field of use growing larger year by year. In the not distant future we can expect to see all our fuels gasified and applied in this form, and the use of solid and liquid fuels condemned as wasteful. By this change in the methods of fuel application, not only are production costs lessened, but our natural resources are conserved. Scientists now tell us that the end of some of our most valuable fuel resources is in sight. It is important then to work together for the conservation and the economical utilization of our fuel resources.—From the Melting Pot.

IMPULSE TURBINE VERSUS REACTION TURBINE FOR HIGH WINDS

(Continued from page 32)

with silt and the only means by which the designer can make provision for coping with it is to so arrange the turbine that easy access may be had to the interior without dismantling generator, shaft or bearings. The overhung construction is entirely suitable in this respect and in combination with renewable clearance rings permits of the operator observing and keeping track of the degree of wear of these rings without taking down the turbine. There are three such turbines, each of 11,300 h.p., operating under a head of 580 ft., at the Maitenes plant on the Rio Colorado, in Chile.—"Engineering."

PULVERIZED FUEL EXPERT ADDRESSES ENGINEERS

Colonel Harlow D. Savage, head of the Pulverized Fuel Department Combustion Engineering Corporation, addressed the Engineering Institute of Canada in Winnipeg, March 15th, on the subject on pulverized fuel, and its application.

Western Canada has shown great interest in this subject and engineers from all over Manitoba and Saskatchewan attended the lecture.

For the past seven or eight years Col. H. D. Savage has been devoting his time to the development of pulverized fuel. At the present time he is probably the most prominent individual in this particular field of engineering endeavor. He has been speaking on this subject for several years past before many of the important engineering organizations in the United States and Canada. His intimate contact with all phases of pulverized fuel development, as well as his ability to put forward the essentials of this method of combustion in a clear and interesting manner, have made his services as a speaker in constant demand.

Col. Savage is a member of the American Society of Mechanical Engineers and of the American Institute of Mining and Metallurgical Engineers.

Big Strides Made in Industrial Electric Heating

Applications of Industrial Electric Ovens and Heating Equipment Extending—Electric Steam Boilers for Special Service Have Aroused Interest

By J. L. McK. YARDLEY
General Engineer to Westinghouse Electric and Manufacturing Company.

CONTINUED progress is being made in the development and application of apparatus for utilizing electric heat in industrial processes. Most striking, perhaps, are the strides which have been made in electric ovens, heat-treating furnaces and electric steam boilers. Arc-type melting and refining furnaces have become well established, and inductive heating has the inherent advantage of generating heat where it is desired, which makes its potentialities considerable. Rivet-heating apparatus has been developed to the point where it can meet moderate demands at low operating expense. Control apparatus for all of the fore-going apparatus has kept pace with these developments so that accurate and reliable operation is practically assured.

The development of the industrial electric oven rests upon a firm engineering and commercial foundation. Applications in the baking of electrical apparatus, foundry cores, japan, enamel and other processes requiring temperatures between 200 deg. and 700 deg. F. are continually extending. In the smaller sizes there is a tendency toward shelf-type ovens and toward vertical or tower construction for the particular purpose of saving floor space and employing some of the generally unutilized overhead spaces. Fortunately this sort of thing may be done in some low-temperature ovens if a relatively light conveying mechanism may be used, as the total weight is not so great but that the whole installation may be carried upon a comparatively light steel framework. Such possibilities are not inherent in industrial furnaces for higher temperature operations, owing especially to the much greater weight of refractories and heat insulation.

Electric Furnace at 2,000 Deg. F.

The industrial electric furnace for heat-treatment operations of many kinds gives increasing indication of coming into its own at no far distant date. In the past there has been considerable disappointment through mistakes and inadequacies in initial constructions and through misapplications, due in all cases observed to insufficient analysis and preliminary consideration of the underlying situation, the exact condition the furnace must meet and the changes in conditions which it would introduce. However, experience and knowledge have multiplied. In the approximately 20 per cent. chromium and 80 per cent. nickel alloy we have a heating element of very long life if it is not mistreated. We have furnace constructions in crucible, pit, chamber and car-bottom types which approach in ruggedness the fuel-fired furnaces without unduly losing in efficiency. However, the details of many process applications must yet be solved by experts. Recent successful installations indicate that, with the help of moderate-priced power, we are honestly entering a period of extensive electrical applications for hardening, tempering, patterning, annealing, cementation or case-hardening and other processes requiring temperatures ranging from 1,800 deg. F. down to, say, 1,200 deg. F. The field for applications of electrical power in heat within this range of temperature is unquestionably one of the largest still potential. The estimate in the N. E. L. A. 1921 Power Sales Bureau report of a potential total connected load in glass annealing of 60,000 kw. covered merely one part of this field.

Electric Furnace at 2,500 Deg. F.

Probably second to the above is the extensive field of forging operations, supplemented by high-speed steel heat-treatment processes, demanding temperatures within the range of 2,000 deg. to 2,400 deg. F. If the possibility of brass melting in the more than 3,600 brass foundries of the country be included, the potential field for electric power in heat at such temperatures is indeed great. Much commendable work, both in design and in application, has been done. More remains to be done in developing furnaces which will be readily and economically applicable to such processes. The engineering difficulties are great, owing particularly to the fact that the only practical resister elements available, carbon and graphite, are rapidly oxidizable at the temperatures required. The resisters must, therefore, be absolutely secluded from oxidizing atmospheres in order to have long life and low maintenance. Hence in these applications the competition of fuel-fired furnaces, and in the case of brass of the arc and induction types of electric furnace, has been more difficult to meet.

The electric steam boiler, which is a special form of electrode-type furnace, has aroused considerable interest during the past year or two. The principle was employed on a big scale over fifteen years ago at Niagara Falls in the three-phase water rheostats which were used for unloading the then largest 12,000-volt alternators while making acceptance tests. It has been incorporated in a number of very simple boiler constructions in which the amount of steam produced, and hence the amount of power consumed, may be controlled, automatically if desired, by regulating the water level. The electric steam boiler may become a very practical and helpful auxiliary to supplement or temporarily supplant the fuel-fired boiler in industries which require large quantities of steam and which are so located geographically as to have available waste or cheap hydro-electric power. The particular field for such boilers in large sizes would appear to be as an auxiliary to hydro-electric systems in territories where it has been found impracticable to approach 100 per cent. load factor with pulp grinding, electrochemical, electrometallurgical or other loads.

It appears more than probable that a host of successful applications will be found for electric steam boilers in small sizes; say 5 boiler-h.p. or less, in locations having moderately priced electric power, generated by steam or water power, in special processes, in isolated parts of industrial plants, in garages, in public buildings, in laundries and domestic use, in climates having only brief and irregular periods of low temperature. Such applications probably must usually be new or isolated or beyond the capacity of existing fuel-fired boiler plants. It is obvious, for instance, that when public service companies such as the Boston Edison Electric Illuminating Company will sell steam in quantities less than the output of a 5-h.p. boiler at $1.35 per 1,000 lbs., and at a smaller price for larger quantities, only very special and exceptional circumstances would permit the existence of an electric steam boiler within reach of its steam lines.

To-day there are probably more than a thousand arc-type melting and refining furnaces in the world, of which more than four hundred are in the United States and employed in the iron and steel industry. The special reasons for the expansion of electric steel making are the reduction of wholesale power rates, the extreme flexibility and adaptability of electric furnaces to a wide range of uses, and the quality of the products. With the electric arc furnace a reducing atmosphere can be maintained which enables the removal of sulphur and manganese sulphide, thus making it possible to readily eliminate oxides. The furnace may be used alone or in conjunction with the Bessemer or open-hearth type, or both. It may also be used in connection with the blast furnace or cupola for making semi-steel, gray iron and malleable-iron castings. Furthermore, it may be operated either acid or basic. The popularity of the arc furnace is increasing most rapidly in the small high-grade steel or iron foundry, owing to its advantages in small units for making frequent small heats. The desirability of relatively high voltage for melting and low voltage for refining is now generally recognized.

Arc Furnace Coming Back

As a means of melting brass the arc-type furnace is attracting increased recognition, the advantage of rapid operation outbalancing the early criticism that the arc would unduly volatilize the non ferrous materials. Possibly the best indication of the sound basis on which this application stands may be read in the recent announcement by one of the oldest and best known builders of fuel-fired melting furnaces for brass of a line of electric furnaces for brass melting employing the arc principles. The construction embodies the familiar pair of horizontal electrodes operated from a single-phase transformer; otherwise it retains the seasoned features of the oil-burning furnace, with some modification perhaps.

The possibilities of inductive heating should be kept in mind since it generates heat directly in the material to be heated. When suitable heat insulation is provided, the temperatures obtainable are limited only by the fusion temperatures of the best refractories.

The high-frequency induction furnace has come as a boon to the scientist engaged in the study of properties of matter at high temperature and under controllable chemical conditions. It is commercially promising for heating in vacuum, for melting silver, gold, platinum and precious alloys, and for melting of very high-grade alloys of steel and nonferrous metals. The units are small, so that a total of over 1,000 kw. installed, or double the amount two years ago, represents a widely diversified field and indicates a growth that appears healthy.

The low-frequency induction furnace is being applied—particularly for commercial uses—in the melting of non-ferrous metals and the production of brass. In fact, some foundries where continuous operation is the rule use this type of furnace only. New modifications of the low-frequency induction type are being brought out from time to time, indicating the interest that is taken in improving this application, although it seems to be on a successful basis already where established.

An example of the employment of commercial frequencies in a somewhat similar manner is found in the type of rivet heater in which the rivet forms a part of the transformer secondary circuit and is heated by the I^2R losses. The outstanding characteristic of this type is that the individual rivet may be heated exactly when wanted. However, constant attendance or close-control mechanism are necessary to prevent burning; otherwise, if the rivet is not required just when expected, then the energy of heating is wasted.

A type of rivet heater which gives promise of becoming popular consists of a chamber capable of holding fifty rivets or so, air-tight, except at the door, perhaps lined with non-oxidizing metal, and surrounded by heating elements and generous heat insulation. Such a heater kept filled with rivets and under pyrometric control is capable of meeting sudden demands for rivets in small quantities at any moment; still, it operates at a very low expense between demands owing to low radiation losses and the absence of attendance.

The regulation of the arc-type furnace, owing to the highly concentrated heat and intense temperature of the arc, must necessarily be controlled by current or kilowatt input. Several effective regulators have become fully developed which will hold the input with sufficient accuracy to a constant value according to the setting. The setting is changed during the cycle by the operator, as determined by the maximum permissible power demand and by the particular melting and refining periods desired for the kind and amount of charge. Induction furnaces require special controlling apparatus. For the resister type of furnaces, at least below 2,500 deg. F., methods of pyrometric control have been fully worked out by which the electrical input in the furnace is controlled according to the temperature of the work itself by means of one or more thermocouples placed in the furnace chamber adjacent to the work. The actual temperature variation below the maximum, within a furnace chamber, over a cycle, of course, depends upon the initial temperature and weight of charge, the amount of stored heat in the furnace walls and the rate at which energy is given up by the heating elements and absorbed by the charge after power is turned on. Radiant-type heating elements disposed as uniformly as possible about the work tend to give up heat at the greatest rate, owing to the resistance to heat flow from the source being a minimum. The maximum chamber temperature and the actual operating temperature after the work has reached the desired temperature are susceptible of the closest possible control by the pyrometric method, inasmuch as commercially available indicating and recording pyrometers are highly sensitive and, through secondary relays, will actuate contactors in the supply circuit upon changes in temperature even so little as one-half of 1 per cent. above and below the setting. The accuracy, flexibility and reliability of pyrometric control, more than anything else probably, constitute the appeal of the industrial electric furnace in heat-treatment processes.—Electrical World.

AIR PRESSURE IN FURNACES

(Continued from page 33)

should not be increased unless lower boiler temperatures are imperatively necessary.

4. Occasionally an engineer will state that a low draft over the fire is hardly worth trying, because he is not operating a modern stoker-fired plant, but a forced draft, hand fired boiler. The idea seems to prevail that only a plant with all the most modern improvements can obtain advantage from low constant draft.

The fact is that a hand-fired forced draft installation usually has a lower percentage CO_2 in the flue gases, and a much higher percentage excess air than a stoker fired installation, because constant opening of the fire doors admits excess air in quantities: Therefore, the hand-fired, forced draft installation would profit by draft control more than the stoker-fired installation. The only limitation is that the damper must be set so that it cannot shut completely when the boiler is being fired.

5. There is a tendency to call the conditions of a low constant draft over the fire "balanced draft." As a matter of fact this term is a trade name, used by a particular manufacturer. Much confusion may be caused by using the term where it is not intended to be used, and the manufacturer responsible for it expressly calls attention to this in his printed matter. Sometimes it is used when there is no "balance" whatever, and much use is distinctly ludicrous. The term should not be used in general discussion of draft conditions.

6. Sad experience with early types of mechanical regulators have made a good many engineers skeptical as to their value, but improvements in this class of apparatus have changed the situation and present types should be thoroughly investigated anew, when the question of low draft over the fire is under consideration.

It is important, in the interest of national economy of fuel, as well as in the interest of individual power plant operators, that a clear understanding of this matter of draft over the fire should be obtained by everyone who has charge of handling fires. Whether oil, coal or blast furnace gas is used for fuel, the same principles apply; so long as the fuel is injected under pressure or is supplied with air under pressure.

The mechanical cleaning of soot from boiler tubes, the application of forced draft to many installations and better methods of treating feed water have all tended to improve the economy of the boiler plant. Such economy will not be complete, however, until the rather substantial losses due to excess air and irregular temperatures are eliminated by some better means than merely endeavoring to make boiler settings tight.

No attempt has been made to discuss here the relative merits of different mechanical methods of obtaining a low draft over the fire. This is a matter for the engineer to study thoroughly before he makes up his mind concerning action to be taken. But the general principle that a low constant draft over the fire effects very real economies with boilers having forced draft and that satisfactory means are at hand for obtaining this economically is one which no engineer can afford to overlook.—"Steam Power."

Cause of Slag Incrustation Upon Boiler Tubes

Demonstrating Furnace and Draught Conditions That Have an Effect Upon Slag Formation—Analysis of Samples Taken at Different Times During Tests

By HARRY H. BATES

SLAG formation on boiler tubes and walls is essentially governed by the same rules as apply to clinker formation, inasmuch that the slag in the iron must be kept in the ferric state which is practically infusible. This can only be done by completely oxidizing the sulphur and iron before the tubes are reached.

All types of stokers have difficulty with slag formation and it is believed that slag particles are carried up with the draft in such minute form that they can be transported by the low-velocity gas as well as by the gas that rises rapidly.

An examination of the slag under the microscope revealed small spherical globules, substantiating the belief that the particularly troublesome particles were the small ones.

When these small particles come in contact with the free oxygen in the furnace gas for a sufficient time to oxidize them completely, they will be transformed into their completely oxidized state and become solid. If they solidify before touching the tubes or walls, they are carried through the boiler as solid ash. On the other hand, no free oxygen is obtained through the fuel bed. In this event the particles remain in a molten condition, on account of their fusing temperature, and are deposited on the tubes and walls where they may either be completely oxidized and solidified or be covered by successive coatings or layers of the same plastic material.

That the latter is true to a large extent is shown by layers of a very dark vitreous material covered by a reddish brown layer or protective coating. This reddish coating is largely ferric material and it prevents further oxidation of the dark ferrous material within by excluding the oxygen from it. A considerable portion of the material on the outer surface, especially on the tubes, is of a friable and non-fusible character, and it is of a completely oxidized nature.

Various efforts have been made for producing complete combustion in large furnaces, but it is pointed out even if some efficient means is developed for mixing the gas and excess air together, it is very questionable whether the slag difficulty will be entirely overcome. It is to be remembered that in addition to the problem of supplying and mixing the oxygen and combustible gases, time is required for the various chemical reactions to take place.

There is but little chance for thoroughly mixing all gases in the combustion chamber, as the rapid rate with which the gases ascend prevents a thorough mixing, so that stratification of the gases results.

In proof of the above, analyses of samples were taken from the first-pass baffle opening of a boiler immediately under the first row of tubes.

These readings showed a carbon dioxide content of from 10.0 per cent. along the walls to 17.5 per cent. in the center. From these figures it can be appreciated that the chances for the ferrous material to change into the ferric state are very few. It was evident that there was an insufficient penetrative effect from the ventilated walls to take care of the wide furnace, and it is also noted that there was considerable excess air along the walls.

Numerous samples of coal ash and slag were analyzed and it was found that the slag on the furnace walls ran much higher in ferrous iron, by per cent., than did the slag on the tubes. In consequence of this the slag on the walls was much freer from the coarse, friable, infusible material than was the material on the tubes.

Numerous theories were advanced during this investigation as to the causes of slag formation on the tubes. Chief among these was the condensation of tarry vapors on the tubes, to which the flying particles could adhere and solidify.

Whether condensation of tar can actually occur is, however, subject to doubt in view of the facts pointed out by the author.

In the large number of tests made it was indicated that the slag deposit on the tubes was nearly proportional to the total amount of gas, and was not greatly affected by the rating. The amount of slag was affected by the temperatures in the furnace, however, for the hotter fires kept the slag in a more viscous state, which greatly increased the tendency for cinders and particles of ash to adhere.

In trying to prevent slag accumulation three methods were considered. Among these the injection of steam into the air supply was tried, but no decrease was noticed in the formation of slag on the tubes. Another method now being tried is that of intimately mixing air with the gases. The original boilers were set about 13 ft. from the grates. It was thought that by increasing the distance between the grates and boiler tubes the gases would have more opportunity to mix thoroughly. Also, since the total time of travel of the furnace gas is dependent upon the velocity and distance of gas travel, more time would be allowed for complete oxidation of the small particles. Consequently a boiler was set up 6 ft. higher than those originally installed.

Assuming that the rapidity with which the gas rises from the fuel bed is uniform, it is calculated that its velocity was about 18 ft. per sec. This is the lowest possible velocity that can be expected. The direction of gas travel is from the grate direct to the baffle opening, which was proportioned as 46 per cent. of the grate surface. Necessarily the velocity was twice as high under the baffle as it was leaving the fuel bed.

On this basis the time it took for particles to reach the tubes with the original installation would be 0.72 sec. This is very little time for oxidization to take place, unless it is of an explosive character. Further, by raising the boiler to 19 ft. this same time would be 1.05 sec., which is still a very short period.

This arrangement has not shown any great improvement in slag prevention and has the disadvantage of exposing more brickwork to high temperatures and to draft, with resulting greater infiltration of air through the setting.

Furnace construction undoubtedly has much to do with the external incrustation of the tubes with slag. The ratio of the exposed tube surface to the grate area was 1 to 1. This is very low and the lower the ratio, under set conditions of fuel and fuel bed, the higher will be the furnace temperature. It is apparent that the higher the furnace temperature, the greater will be the tendency for the ash to fuse and stick.

It has become common practice now to have the ratio of exposed tube surface to grate surface as high as 1.87 to 1, and it is seldom less than 1.2 to 1. By increasing this ratio the amount of heat radiated up and absorbed is very materially increased, with a consequent reduction in furnace temperature. This last item, namely, furnace construction, is a step in the right direction.

It is extremely fortunate that only a comparatively few coals give slag trouble to a serious degree. A great many coals have fusing temperatures so high that they give no trouble with ordinary furnace temperatures. Another class of coals have low fusing temperatures, but do not seem to have the tendency to be lifted from the fuel bed. But when a coal gives serious slag trouble, with the present knowledge of

New Element Discovered

IT IS surprising to what degree of accuracy we can prophesy the discovery of a new element long before it is actually detected by our chemists. We know through the use of X-ray spectroscopy, that all chemical elements can be arranged in perfect rotation ranging from hydrogen with its atomic weight as one, right through the list of elements until we arrive at the last element on the list which represents the heaviest atom known and which bears the name of uranium. Thus our list of elements is complete in information, inasmuch that we know the position of each element, its atomic weight, and also a few of its chemical and physical characteristics, even before we have actually isolated this element in the chemical laboratory. This information is obtained through an analysis of the spectrum of various compounds, which has in its constitution a trace of the rarer element. The only means of tracing this is on the diagram of the spectroscope, even though the element has never before been seen or separated from its complex mass.

Until just recently, there were five such elements missing from our list, or perhaps it would be more correct to say instead of missing, that these elements had been identified, but not completely isolated or discovered. Now we are informed that the list has been made more complete by the discovery or isolation of a new element which has filled one of the gaps on the list, and which element has been given the name of hafnium. This element conforms in all particulars to one of the missing elements, and located in position seventy-two on the list, which number also signifies its atomic weight. This metal was discovered by Professor A. Scott, Director of Science at the British Museum, who, we are informed, detected this new element first in some peculiar black sands from New Zealand and from which he was successful in obtaining an oxide of the new element, which is the first that has been ever produced. It is a little too early in the day to speak about the possible uses for this new metal, but it is suggested that it may possibly be used in the manufacture of filaments for incandescent lamps and also for making crucibles.

Salinity Indicator

MOST marine engineers are familiar with the difficulties associated with the operation of an evaporator, and the constant attention required to insure that priming does not take place. There has been no means up to the present, whereby an engineer can tell at a glance the density of the water, without the usual hot and objectionable procedure of drawing off a portion of the water and testing it out with a salinometer. The same condition applies to a boiler where the circulating water in the condensor of the engine is salt, and a leakage would mean an increase in the density of the water in the boiler with its consequent ill results, if not caught in time. How often has an unsuspecting engineer taken it for granted that everything was in order when he suddenly realizes the density of his boiler is up. This is now a thing of the past, as a salinity indicator has recently been introduced that instantaneously and automatically indicates the density of the water by the use of a series of coloured lights. This is effected by means of a signal light controller and can be applied either in conjunction with an evaporator, or in a slightly modified and much more sensitive manner, directly with a condensor where the slightest leakage is immediately detected. This visible indication of the actual density condition, is conducive to much more satisfactory results since the chlorine contents are immediately indicated by a predetermined light colour, which should make operating conditions much more reliable than have hitherto been obtainable in the boiler or engine room, and at the same time make the position of the engineer a much more comfortable one.

Autogenous Welding

DURING the last decade, great strides have been made in the methods of making an autogenous weld. Further developments have been made just recently when a new process was demonstrated before the representatives of a large number of engineering and shipbuilding companies in Great Britain. In this process which is for both welding and cutting, hydrogen is used in combination with a 50 per cent. mixture of gasoline and benzol, and it is claimed that great economy is effected by the adoption of this combination, on account of the considerable reduction in oxygen costs. Tests were made upon cast iron, aluminum and steel and in the case of the latter, a ¾-inch boiler plate seventy-four inches long was cut through on a consumption of ¼-pint of gasoline-benzol mixture in less than eight minutes.

It is interesting to note among the advantages claimed, that this process can be operated without the generation of noxious fumes. It is stated that it can also be operated with such perfect safety, that an unskilled or unexperienced operator can use the apparatus without fear of an explosion. There are certainly points worthy of consideration in the selection of such an outfit, and one that we feel will be appreciated by the employer.

One advantage claimed by this system, is that the rough surface that is usually produced by the result of a torch cut, is perfectly soft and readily removed by a file. We are not, however, informed whether the physical properties of the metal are affected in any other way and whether segregation takes place.

Our Question Box

Commercial Rating of Boiler

Question.—Would you kindly inform me the rule that is used for obtaining the commercial rating of a boiler horsepower.

Answer.—This can be approximately determined by estimating the number of square feet of heating surface per boiler horsepower; or it may be calculated according to ratio of grate surface per horsepower. The heating surface of a boiler means that part of the boiler where heat is applied to one side and the water is on the opposite side. In a locomotive portable boiler, the heating surfaces comprise the internal surfaces of tubes, inside firebox sheets, as the crown sheet, wrapper plate, door sheet, firebox tube sheet, except the area taken up by the tubes, etc. The following table gives the estimated grate to heating surface per boiler horsepower: Heating Surf. per Horsepower in Sq. ft.

Type of boiler	
Locomotive	12 to 15
Watertube	11 to 12
Horizontal return tubular	12 to 14
Vertical	10 to 12
Flue	8 to 12

Heating Surf. to 1 Sq. ft. of Grate Area

Type of Boiler	
Locomotive	50 to 100
Watertube	35 to 40
Horizontal return tubular	25 to 35
Vertical	25 to 30
Flue	20 to 25

Having determined the heating surface of the boiler, divide the total effective heating surface by the unit of heating surface estimated to produce a boiler horsepower.

Take for instance, a portable locomotive boiler has an effective heating surface 900 sq. ft. As the horse power rating of this boiler is considered as of 12 sq. ft. of heating surface, the commercial horse power will be

900 divided by 12=75 H.P.

The actual boiler horsepower depends on the amount of water evaporated per hour. The unit of boiler horsepower is the evaporation of 30 pounds of water per hour from a feedwater temperature of 100 degrees Fahrenheit into steam at 70 pounds gage pressure. This is equivalent to the evaporation of 34.5 pounds of water at 212 degrees Fahrenheit into steam of the same temperature at atmospheric pressure. Boilers generate steam at different pressures and feedwater is fed into the boilers at different temperatures so these conditions must be taken into account in making boiler comparisons and in estimating the horsepower.

For this purpose a factor of evaporation is employed. This factor of evaporation is the ratio of the amount of heat required to make a pound of steam under actual working conditions to that required to produce a pound of steam from a feedwater temperature at 212 degrees into steam at atmospheric pressure. This is found by subtracting the heat units in one pound of feedwater at the given temperature from the heat units in one pound of steam at the working pressure. This difference is divided by 965.7, the number of British thermal units in one pound of water evaporated from and at 212 degrees F. Engineers' hand-books give the table covering the factors of evaporation, which are used in making boiler horsepower calculations. If for example a boiler evaporates 10,000 pounds of water per hour from a feedwater temperature of 70 degrees F. at a steam pressure of 100 pounds per square inch, gage, the factor of evaporation given in the table of factors of evaporation equals 1.188. This factor indicates that if the feedwater had been 212 degrees F. and evaporated into steam at the same temperature, or at atmospheric pressure the boiler could have evaporated 10,000 x 1.188=11,880 pounds of water, which is called the equivalent evaporation. Since one boiler horsepower is the evaporation of 34.5 pounds of water per hour at 212 degrees F. with steam at the same temperature, the horsepower of any boiler is determined by dividing the equivalent evaporation by 34.5, and in this example 11,880 ÷ 34.5=344.3 boiler horsepower.

Work Effected by Pump

Question:—We have a large water tank having a capacity of 100,000 gallons from which water is being constantly used, and wherein it is impossible to tell the exact amount. There is a pump in constant service pumping this tank up. Could you tell me how many gallons per minute and per day, this pump discharges into the tank, the pump having a plunger of 9¼ inches diameter, 14 inch stroke and having 38 strokes per minute.

J. P. T.

Answer:—If the pump is working at a constant speed, it will be an easy matter to find out the number of gallons displaced in one minute and also in 24 hours. We do not, however, know the efficiency of the pump, which can be fairly well judged by its condition, if a test has not been made. We will, therefore, presume the pump to be 100 per cent. efficient and J. P. T. must deduct a certain percentage from our figures to allow for leakage.

The plunger having a diameter of 9¼ inches, the area in sq. inches will be 9.25 × 9.25 × 9.25 × .7854 = 67.2 and the volume displaced each stroke will be 67.2 × 14, which is multiplying the area by the stroke in inches, which gives us 940.81 cubic inches per stroke. If this is multiplied by the revolutions or strokes which are 38 and divided by 1728 (cubic inches in one cubic foot) we get 20.6 cubic feet per minute, which multiplied by 6.24 (gallons in a cubic foot) we get 128.73 gallons per minute. For gallons per day multiply this by 1440 which gives us 185,381 gallons per day.

$$\frac{9.25^2 \times .7854 \times 14 \times 38 \times 6.24}{1728} = 185,381$$

gallons per day.

Compressed Air

Question.—What is the principle of compressed air as applied to refrigerations?

A. T. M.

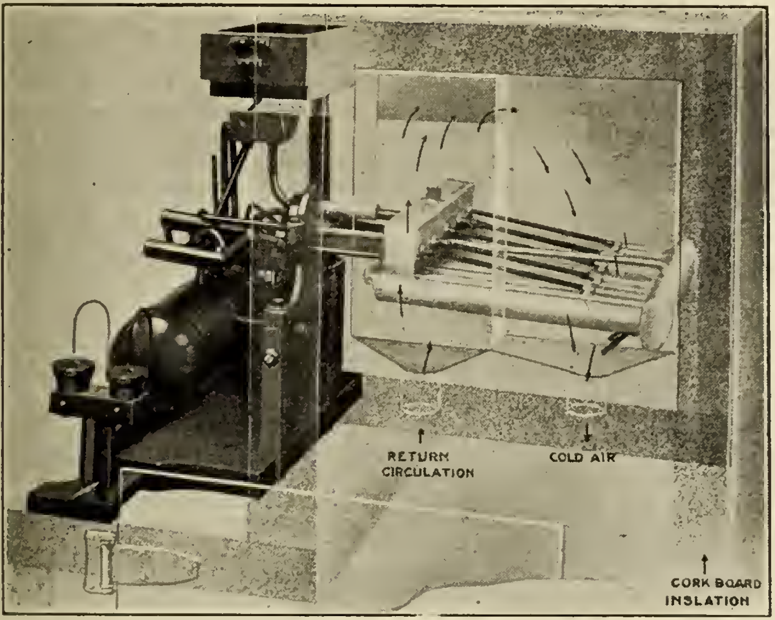
Answer.—In the first place it must be understood that in order to effectively expand a gas, it must absorb heat, and secondly, that the act of compressing a gas generates heat. If therefore a compressed gas is re-expanded it absorbs the heat lost during the process of compression, but if the compressed gas has already been cooled down, it is evident it will not contain sufficient heat to effect its own expansion, and it will therefore have to extract the necessary heat from its own surroundings and by so doing it will considerably reduce its temperature. If, for instance, 1 lb. of air at 14.7 lbs. absolute pressure and 60 deg. Fahr. is compressed to 110 absolute pressure, its temperature will be raised to 475 deg. Fahr. This compressed air is now cooled down to 6 deg. Fahr. or through 410 deg. Fahr. (475 deg. — 65 deg.), as the specific heat of air is .238, the number of thermal units that have been extracted from the air are 97.58 (410 × .238). When this cool compressed air is now re-expanded to 14.7 lbs. absolute, it will have to absorb 97.58 B. t. u.'s. Since the extraction of 170 thermal units from 1 lb. of water at 60 deg. Fahr. converts it into ice, it is evident that if the 1 lb. of compressed air at 65 deg. Fahr. is expanded surrounded by .574 lbs. of water (97.58 ÷ 170) at 60 deg. Fahr., it will also be converted into ice.

Progress in New Equipment

Iceless Refrigerator

An electric refrigerator has been recently developed, that has no working parts and still is operated by electricity and produces its own ice. The actual ice making apparatus itself is very small and is as simple as the two principles which it employs. The first is—that pure liquid ammonia whilst evaporating, chills the surrounding air, just as your finger feels cold when moistened and held in the wind, allowing the moisture to evaporate. The difference is that liquid ammonia chills in a very much more marked degree. The second principle is that evaporated ammonia is absorbed by water very easily and readily, and in large volumes.

Referring to the illustrations: on the left hand side in the tank, is about two quarts of ordinary ammonia such as is purchased for home use. Within the tank there is also a small electric heater. When the heater is started the gas is driven out of the water. This gas is not very warm, as ammonia is very easily driven off, and when it flows over into the pipes shown on the right of the illustration it is chilled by a trickle of cold water which is flowing over the pipes. When it is chilled the gas is deposited on the inside of the pipes, about the same as dew is deposited by the chill of the morning air. This deposit is pure liquid ammonia. When the pipes are nearly full of the pure liquid ammonia, the weight is sufficient to swing the pipes down, raising the tank and shutting off the electric heater. Almost immediately pure liquid ammonia begins to evaporate and to chill the pipes, which in turn, chill the surrounding air which flows down into the refrigerator. As the pure liquid ammonia evaporates it flows back as a gas into the tank of water, where it is quickly absorbed. As soon as the evaporation is completed the pipes, having become lighter and the tank heavier, the apparatus tilts back to the original position and the electric heater starts again. The operation is automatic. The mechanism can be arranged for either chilling the air or freezing the water into ice cubes for table use, which latter process is just a little more costly. The amount of electrical energy consumed varies from 2.7 to 3.8 kilowatt hours per day, continuous operation. These refrigerators are made by the Keith Electric Refrigerator Co., Toronto, Ont.



Operating mechanism of the iceless refrigerator.

Ames No. 55 Simplified Dial Gauge

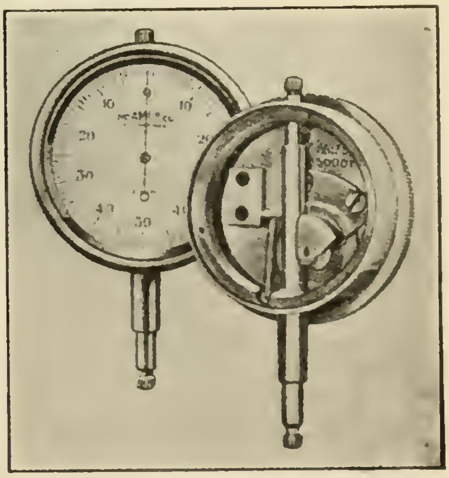
The simplified dial gauge or indicator shown in the accompanying illustration is a recent addition to the line of gauges produced by the B. C. Ames Co., Waltham, Mass. It embodies several marked improvements in construction and design over the previous type, such as simplicity, durability, accuracy and interchangeability.

The No. 55 dial gauge has only 39 [illegible] as compared with 55 parts [illegible] gauge made by the same firm. Simplicity has been gained by putting both the rack wheel and the take-up wheel with the spring all on one large staff, and thus using only one bridge to support these parts and the center pinion. The design of the bezel eliminates other parts such as lugs and lug screws, since the bezel is held onto the case by one piece of spring brass wire. The elimination of these parts has made the mechanism more durable and accurate since there are fewer parts to wear, break, get out of order or replace.

The gauge can be badly abused and yet retain its smooth spindle action and accuracy. The manufacturer claims that it can be dropped from a height of 5 ft. or even more to the floor, so that contact is applied to the plunger, without injury to the instrument; and that the case may be battered out of shape, and still the gauge will function perfectly. This is made possible chiefly because the wheel staff is very large and the spindle is so designed that the shoulder thereon comes in contact with the top of the case to receive the shock.

A tolerance of only 0.0005 in. plus or minus is allowed in the entire spindle travel, and any gauge showing a greater inaccuracy is rejected at the factory. All parts are made with jigs and to standards, so that parts substituted at any future time will fit perfectly. The screw and other parts have all been constructed larger than before, thus making assembling and disassembling easier and simpler.

The bridge is made of thick pressed brass and the guide block of solid brass. The case and back are similar to those on the No. 5 gauge. The spindle travels 0.3 in. The dial is usually graduated into 100 parts, reading 0.050 in. each way. By using a special rack wheel, the dial can be divided into 50 parts, the marks being twice as far apart. Special dials and spindles can be supplied.



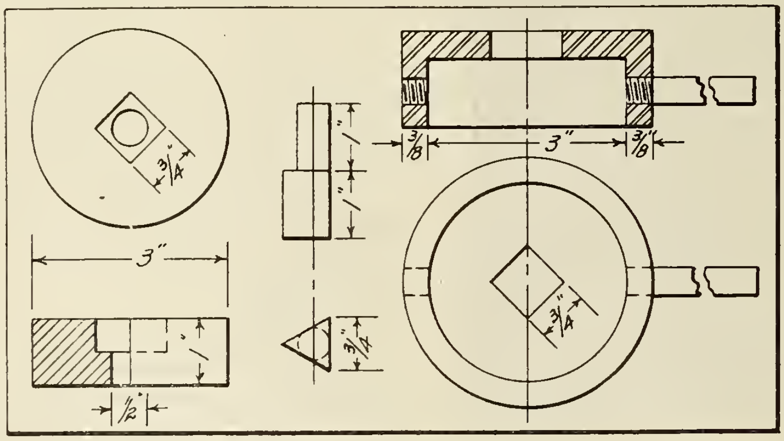
No. 55 Simplified Dial Gauge.

The Operator's Point of View

Drilling Square Hole

By F. Hindle

The accompanying sketch shows the method of holding 3 in. discs while recessing out the square hole as indicated at A. The block is one of a number of forge machine die heads that were required to the dimensions given. The square section was drilled out by using the jig and triangular drill bit. A piece of tool steel large enough to make the triangular portion was selected and turned on one end to fit the drill chuck. The triangle was then milled with one side equal to that of the side of square required. After the jig and drill were made and hardened the drill bit was ground until it turned freely in the square hole of jig. When in operation the jig is allowed to float on the drill table, the handle serving as a stop. The ½ in. hole was first drilled through the center of the 3 in. block.



Gear for Drilling Square Holes.

Double the Life of Electric Bulbs

A great number of electric bulbs, which are considered as being burnt out and useless, can be quite easily repaired, by knitting together the broken ends of the filament, and the bulb will last as long again. If, however, the bulb is fogged, (white or yellowish-white) or if there are pieces of hair-like filament loose in the bulb, it is useless, since the ends cannot be brought together.

Electric Bulbs

It is best to work in daylight and behind a pane of clear glass, such as may be in a cupboard door, or by raising a window, so that the pane of glass will protect the face, eyes, of the worker,—if bulb should happen to burst,—which is quite unlikely. Simply screw bulb in socket (an extension makes it more convenient) and turn on the current. Now move bulb about so as to bring the two broken ends of the filament together. As it connects, the bulb will light. Leave bulb burning for a minute. Turn off current and turn on again and it will found that the filament has been knitted or welded together.—M. E. Franklin.

Little Losses Often Costly

By W. F. Schaphorst

It is a pretty safe bet, in most establishments where power is used, that the simple little losses when added together amount to more than the single big loss that, because of its bigness, can be plainly seen. Besides, the cost of eliminating the small losses may amount to considerably less than the cost of eliminating the big loss. The writer is more familiar with power transmission by belt and ropes than with most other mill equipment hence his mind usually thinks in terms of belts, ropes, shafting, pulleys, etc. Nevertheless, the little losses in other departments are of equal importance. There is too much lost motion wherever you go. Too much friction not only between shaft and bearings but between human beings.

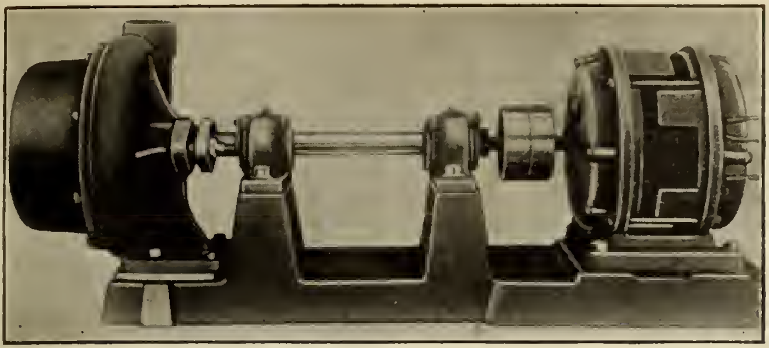
For example the head miller finds that a machine isn't running fast enough. It is 5 per cent. too slow. He cannot speed it up faster because it was made for one speed and only one. The foreman may not know it, but in addition to the 5 per cent. production loss there is a 5 per cent. power loss. The driving engine or motor is doing just as much work as though it were pulling a full load. The actual load of the driven machine plus the power loss due to belt slip is equal to the full normal load without slip. However, the head miller knows or feels that production could be increased by spending a few cents to treat the belts and make them pull without slipping. Or, he would spend a little more and use some larger pulleys. He knows that large pulleys are not so liable to slip.

He, therefore, goes to the manager and suggests the improvement. The manager, however, is a balky person. He tells the head miller that he doesn't know what he's talking about—that everything is O. K. aside from the slight 5 per cent. production loss. He says to the head miller, "If we wanted to increase the speed by that 5 per cent. we would buy a larger driving pulley for $30 but it wouldn't pay. It's too much trouble." There the matter rests. In the above case a new $30 pulley wasn't needed at all. About 5 cents' worth of belt treatment would have put the belt in proper condition to do full work without slipping. The manager, you see, proposed to spend $30 and at the same time continue to pay for the constant power loss of 5 per cent. which might amount to another $30 per year, plus the cost of wear and tear on the slipping belt. Little losses, surely, are worth investigating and stopping, if it is possible to do so at slight expense.

Electric Steam Boilers

Equipment for generating steam with electric power has aroused interest in various parts of the country, especially where fuel is scarce and surplus water power is available at a low rate. High tension electric steam generators have been installed to the extent of 150,000 kw. in the past year and are operating at 99 per cent. efficiency, according to the manufacturer. One big advantage of such boilers is their lower first cost compared with fuel-fired boilers and their flexibility and ease of control. Another electric steam generator has been developed which is also extremely simple, reliable, compact and high in efficiency. Its chief difference from those previously developed is a separation of the steam generating space from the hot well and the provision of adjustable circulation between the two which enables regulation for steam demand and energy input and facilities forcing.

Albert W. Honywill, Jr., has severed his connections with the Terry Steam Turbine Company, at Hartford, Conn., to take up new duties as assistant to the president of the Diamond Specialty, Ltd., of Windsor.



Motor-driven centrifugal pump.

Motor-Driven Centrifugal Pump

A ball-bearing, motor-driven, self-priming centrifugal unit for pumping liquids such as coolant compounds, oils, brines and enamels, has recently been placed on the market. This pump is similar in design to others of the same make except that this latest model is equipped throughout with ball-bearings, and has a capacity of 75 gal. per min. Intake and discharge openings are located at the top so that sufficient fluid is retained in the pump chamber for priming; no valves or other mechanical appliance is necessary. Flow starts as soon as the unit is placed in operation. The pump can be regulated to discharge any given quantity, from a few drops per minute to the full capacity. These pumps are made by the Fulflo Specialties Co., Blanchester, Ohio.

The Amateur Inventor

John S. Watts

The desire to get rich quick is the underlying cause of at least ninety per cent. of the abortive inventions which flood our patent offices. Out of all the mass of patents granted, it has been stated that only three per cent. are successful, a statement which my experience leads me to believe to be approximately true. The main reason for this seems to be that although the bulk of these so-called inventions are of mechanical contrivances, the inventors themselves are generally men who are only indirectly connected with mechanical work, such as salesmen, bookkeepers, etc. In the nature of things, and in this mechanical age, the largest field open for new ideas of a patentable character is naturally in the mechanical arts.

The variety of machinery, such as typewriters, sewing machines, autos, radio phones, etc., which the ingenuity of engineers has made available in such form that they can be operated by any intelligent person, has had a tendency to impart to the non-technical operator a feeling of familiarity with machinery, based wholly on his ability to operate such machines, and a very slight acquaintance with their mechanism acquired by the curiosity engendered by its use. To the mechanic it is amusing to note how the owner of an auto who has successfully taken some part adrift and got it together again, will, on the strength of this simple feat, give himself the airs of a full-fledged mechanic, and plainly indicate his feeling of confidence in his ability to criticize and improve on the work of an automobile designer.

As an illustration of this, I would cite the case of an automobile salesman who conceived the idea of having the blades on the radiator fan made adjustable in order that in cold weather the blades might be set neutral so as not to draw cold air into the radiator, or even reversed to blow air from inside the hood through the radiator. The inventor patented the idea and had a model made, which he submitted to a manufacturing concern with a proposal that they should manufacture the fan on a royalty basis, and employ him as salesman. This firm consulted me for advice on the subject, and for an estimate of the cost of redesigning the fan to make it a feasible proposition, the model being a very crude thing and obviously impractical.

Like most of the non-technical man's patents all that could be said in its favor was that it embodied the idea of something that might be useful if it could be accomplished, but that the inventor had not really invented anything, as the idea as it stood was not practicable, firstly because it would cost too much to manufacture, and when made would soon rattle itself to pieces; secondly, no chauffeur would be bothered with adjusting a fan that required his stopping the car and getting out to lift the bonnet to get at it every time the fan needed adjusting; thirdly, that while having the fan blades set at neutral would assist in getting the engine warmed up quickly when starting, to set the fan blades reversed with the idea that this would warm up the engine by taking heat from it to warm the radiator is as absurd as trying to raise ourselves by tugging at our own boot-straps.

I handed in an estimate for making a workable design, arranged for manipulation of the fan from the dash-board, and there the matter still rests, as the inventor had spent all his money getting the patent and having a model made. The poor devil was quite enthusiastic about his scheme, as these fellows usually are, and bringing him to face the facts was an unpleasant business. Indeed, about the work I dread most is that of advising upon patents, as they are generally worthless, or at best are only a crude idea needing considerable expense to make workable, and to kill the inventor's wild enthusiasm is a painful business for which one is rarely paid, even in thanks. Indeed, in many cases I have known my advice has been received with scepticism as being due to professional jealousy, or even imputed to a desire to steal a valuable? invention, by discouraging the original inventor. It seems as though in the overwhelming enthusiasm of giving birth to their invention, they could blind themselves to its weaknesses, just as a mother can see nothing but beauty in her new-born child, although to outsiders the said child looks rather more like a boiled lobster than a future president.

My latest experience with patents is rather amusing. The invention was an automatic gate for railroad level crossings, "invented" by a miner and financed by a doctor. The general idea was to have a lever which would be struck by a wheel of the locomotive, and the movement of this lever being transmitted in some undetermined manner would open and close the gates. There was no drawing of the invention, merely a rough wooden model, which worked, of course, beautifully. But a moment's consideration would show that a train striking this lever at any speed would simply break it off, or the train would go off the track. Even if the lever could be made to stand the blow or force required to start it from rest to a speed of perhaps sixty miles an hour instantly, which would require an infinite force, the gate arms, being some twenty feet long, would move with a velocity of about one thousand miles per hour, which would be absurd. Then again, even if all this were possible, consider the added excitement of joy riding across a level crossing, never knowing when the gate arms would come crashing down on one without warning at a speed exceeding that of sound.

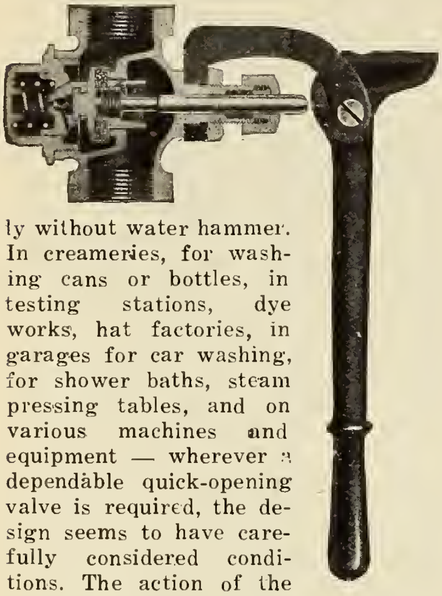
NEW PUBLICATION

Steam Turbine Principles and Practice, cloth bound 5½ in. x 8 in., 350 pages, 282 illustrations published by McGraw-Hill Book Co., Inc., 370 Seventh Avenue, New York. First Edition. This book treats with the subject most fully from the time of the first turbine, 150 B. C., through its successive stages until the present day. It is divided up into 14 divisions; at the end of each, there are questions to be answered dealing with problems from the various chapters. The book is essentially written for the operator, or the man who wishes to know sufficient about turbines to make a purchase and all calculations can be easily followed with those who have a working knowledge of arithmetic.

Waterman-Waterbury Mfg. Co., Regina, Sask., will construct a warehouse and office building. Work will be started immediately. Approximate cost $40,000. Further units will be added as required.

WATER HAMMERLESS VALVES

Adapted to a wide variety of special purposes, it is claimed for the recently-perfected Jenkins Rapid Action valves that they were designed to meet demand for a valve that would act instantaneously without water hammer. In creameries, for washing cans or bottles, in testing stations, dye works, hat factories, in garages for car washing, for shower baths, steam pressing tables, and on various machines and equipment — wherever a dependable quick-opening valve is required, the design seems to have carefully considered conditions. The action of the valve does not depend upon set screws, locking devices or other appliances. When given a pull, equivalent to a quarter turn, the hand lever bears on the end of the spindle, forcing the disc from the seat and opening the valve. Aligning as it does with the spindle, the lever positively holds the valve open. A slight pull on the lever will throw it out of alignment with the spindle, and the disc is then immediately forced on the seat. The closing of the disc on the seat is regulated to avoid water hammer through a combination of spring, piston, cylinder and water pressure. Herewith is a sectional illustration showing how spring and pressure in the line hold the disc on the seat. The valve is made of high grade bronze mixture, fitted with Jenkins renewable composition disc, the spindle is made of steel, the yoke steel forged, and the lever of malleable iron. The end of spindle and cam on lever are especially hardened to prevent wear. The valve has a slip-on type of disc holder, making it possible to change the disc very rapidly.



CAUSE OF SLAG ENCRUSTATION

(Continued from page 38)

the art of burning coal, means must be provided for its mechanical removal. This, however, is not as serious a matter as it appears, for soot blowing in boiler plants is now recognized as a necessity, and apparatus for soot removal is now installed as regular boiler equipment.

Elmira, Ont.—Mr. A. M. Bowman, local hydro superintendent, states that the increasing power load has necessitated the purchase of new transformers.

IRVING SUBWAY FLOORING

In these days when industrial economics seek to combine safety, service and sanitation, Irving Iron Works, Long Island City, N. Y., are making distinctive claims for their Irving Subway flooring. Advantages are summarized as follows:

A complete sectional open flooring—as safe and comfortable and noiseless to walk or work or wheel upon as the best solid floor.

A surface absolutely and permanently non-slipping, even with oil, grease, soap or water upon it.

Fire-proof, non-warping, shock-proof, non-chipping, non-dusting.

80 per cent. open space for light and air to pass—a cool floor to work on or under.

Clean, sanitary, non-dirt-collecting, yet with openings too small for tools or large objects to pass through.

Openings for pipes, columns, etc., easily cut out without seemingly impairing the strength of the panel.

Wheels, trucks, barrows, and rib-hooped barrels easily rolled over it in any direction.

Easily and quickly installed in any type of construction without drilling or tapping, screws or bolts.

A general-purpose flooring adapted to probably 75 per cent. of the places where flooring is used in industrial and engineering construction.

Irving Iron Works also manufacture the Sofstep, an all-steel, self-contained unit with its own carrier, drilled ready for mounting in stairs or ladders. It is said to be non-slipping, time-proof and wear-proof.

TRANSFORMER BROCHURE

Brush Electrical Engineering Co., Falcon Works, Loughborough, Eng., issued a transformer brochure, descriptive of Brush static transformers. This company have standardized definitely on the core type of transformer for single-phase and three-phase alike, claiming certain advantages in definite temperature regulation, ease of repair, and less danger to distortion of circular-wound coils in the event of heavy currents flowing in the windings. The Brush company also manufacture transformers for special service.

Testing Feed Water for Corrosiveness

Place a small quantity of the water to be tested into a glass tumbler, and add a few drops of methyl orange. Then the water will turn pink, if the water contains acid.—Steam, Feb., 1923.

Uehling Instrument Company, Paterson, N. J., manufacturers of CO_2 recording instruments, have appointed the Combustion Engineering Corporation, Ltd., head office, Toronto, and branches in Montreal, Winnipeg and Vancouver, as their Canadian engineers and sales agents.

That the purchasing department of the Central Division of Canadian National Railways may be located in Toronto, is the current report. Purchasing agents will welcome this as indicating that they are not to lose that contract with the National system which they have secured during location of general offices in Toronto. The Central Division is described as extending from Chicago on the west to Riviere du Loup on the east and will have to do with the most thickly-populated section of the country. Nationally, more extensive purchases are made for this section than for any other. Although the tender system throws prospective purchases open to the entire market, selling agents feel that direct contact is an important consideration.

Hamilton.—National Steel Car Corporation, Hamilton, have orders on hand at the present time for new work with the Canadian Pacific Railway and the Canadian National Railways, and for repair work with the Canadian National and Temiskaming and Northern Ontario Rly. Commission; also for some export repair work for the Erie Railroad of the United States. The Corporation reports that the outlook is brighter than it has been for the past few years.

It is reported that the Canadian Car & Foundries Co., Ltd., will vacate their present premises on the ninth floor of the Transportation Building, Montreal, May 1, to take up extensive offices in the building they have acquired near the north-east corner of Craig Street and Victoria Square. This building is four storeys high, of spacious dimensions, with stone front. The frontage is at present being remodeled.

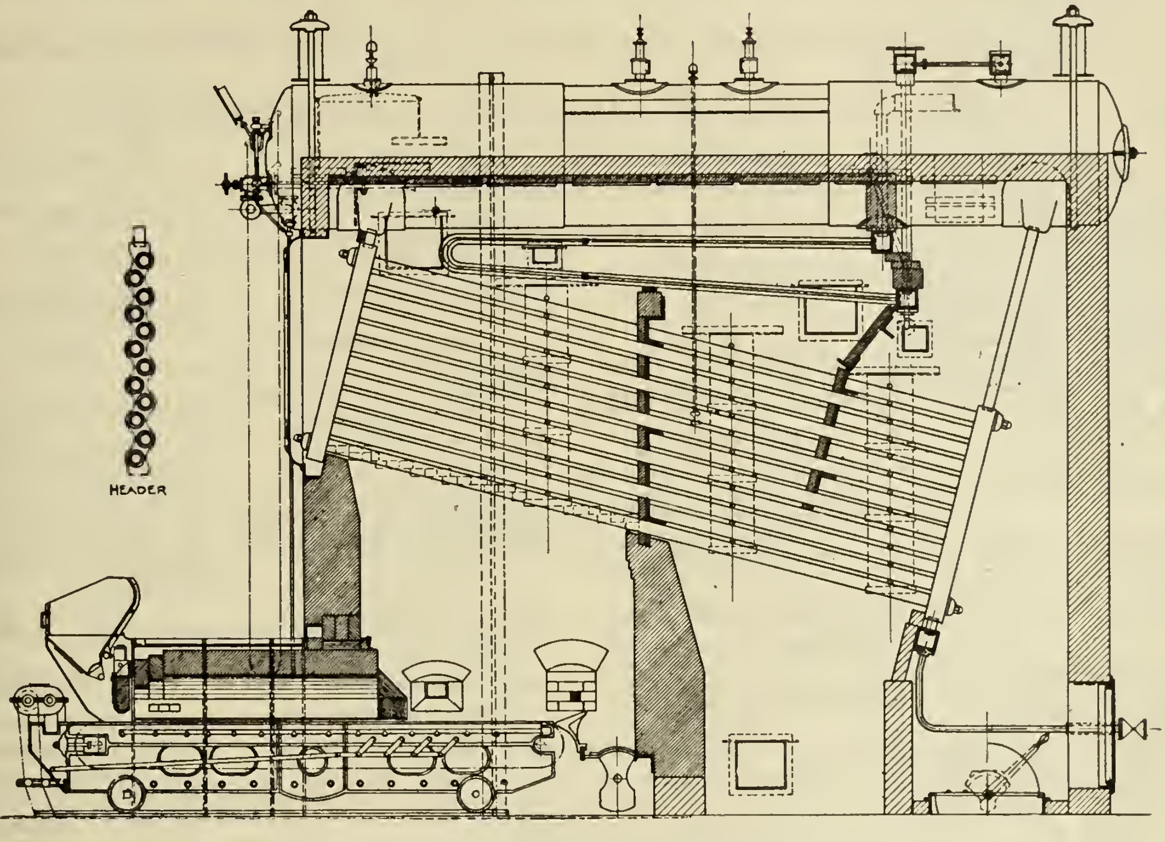
Canadian Fairbanks-Morse Co., Ltd., have made arrangements with the Henry Pels & Co., of New York, for the sale and distribution of their metal working machinery in the Province of Ontario.

Canadian companies incorporated during the past week include the following: The Combustion Engineering Corporation, Ltd., Toronto, Ont.; The National Meter Co. of Canada, Ltd., Toronto.

A. F. White, who has been connected with the Marsh Engineering Co., Belleville, Ont., as general superintendent for the past ten years, has been appointed Toronto sales manager for the John Inglis Co. Mr. White commenced his new duties March 1.

Plans for the further extension of the Canada Gas & Electric Corporation, now supplying Brandon, Man., with electricity, have recently been made by J. R. Harvey, manager. Approximately $400,000 will be spent. Included in the expenditure list is the installation of three new 500 h. p. boilers burning lignite, in the little Saskatchewan plant on the Saskatchewan river. Completion of the power plant will enable the development of 4,000,000 k. w. The highest amount ever generated there is about 500,000 k. w.

BOILER EFFICIENCY



Standard Longitudinal Drum Sectional Header Boiler

The laws of each province provide that every boiler operated within its boundaries must be built to certain recognized standards. All details such as seams, riveting, fittings, etc., must meet the approval of their inspectors before they will pass any boiler as safe to operate.

The Civil Law also states the lowest grade of engineer you can employ and how often he is required to prepare each boiler for inspection.

The lawmakers are concerned with the safety of the public, they do not make it compulsory for you to buy economical plant. You are expected, on your own judgment as a business man, to buy boilers which will give you the highest degree of safety and the greatest return for your money in pounds of water evaporated.

Now just as there are Civil Laws to make sure no unnecessary risks are taken by the public, so there are certain acknowledged engineering laws for the design and construction of economical boilers and furnaces. The success of all such equipment depends upon the success with which these laws, which safeguard your money, are applied—practically.

Boilers made by B. & W. are readily accepted by the authorities, even in the provinces with the stiffest requirements, because they are designed with a higher factor of safety than asked for, and no steam apparatus is made of better material or with more care. Every part is readily accessible inside and out, and with a responsible man in charge to see they are kept clean, there is little possibility of serious trouble.

As regards the efficiency of B. & W. steam plant, we can only ask you here to consider two factors—(1) THE EFFICIENT FURNACE because the fuel is fed evenly and intermixed with a proper amount of air while burning. Perfect combustion is produced and the fuel all gasified in the large combustion chamber before the heating surfaces are reached. (2) THE EFFICIENT HEATING SURFACE because of the proper circulation of the water and hot gases with reference to each other, and because they thoroughly interpenetrate each other, due to the arrangement of the baffles and the manner in which the tubes are staggered.

Babcock & Wilcox, Limited

FOR SALE
Fuel Oil Storage Tank
10,000 GALS. CAPACITY
This is a new tank. We have not yet taken delivery of it, and offer it at a very attractive price.
MR. VOGAN, The MacLean Publishing Co.,Ltd, 143 University Ave., TORONTO.

FOR SALE

TAYLOR SAFES FOR SALE—RARE OPPORTUNITY to secure a safe at small cost. They are in splendid condition. Inside dimensions and prices are as follows: 15″ deep, 2 ft. 6″ wide, 3 ft. 11½″ high, fitted with built-in compartment. Price $250.00. 18″ deep, 2 ft. 8″ wide, 4 ft. 5″ high, fitted with steel compartment. Price $200.00. Apply Box 10, POWER HOUSE.

FOR SALE

BOILERS FOR SALE CHEAP—TWO 100 horsepower, 110 pound steam. Apply Box 102 Power House.

BURNHAM STEAM PRESSURE PUMP, 10 IN. x 1⅛-inch. x 12 in., nearly new, with Fisher governor attached. W. Ahearn, 538 McLaren St., Ottawa. When answering this advertisement please mention this paper. P.F.H.

FOR SALE—ONE 10 H.P. STEAM BOILER with base and 20 ft. smokestack; new flues and in A1 condition; also 1 steam turbine bottle washer and sterilizer; both in excellent working order Apply Box 103 Power House.

INDUCTION MOTOR — 220 VOLTS — 1800 r.p.m. 15 h.p.; single phase; can be bought cheap; write for particulars. Box 104, Power House.

I. H.C. 12 H.P. GAS ENGINE FOR SALE—ALL in good running shape, with 33-inch clutch pulley; will be sold reasonable on easy terms. Apply W. Harrison & Son, R. R. No. 5, Guelph. When answering this advertisement, please mention this paper. P.F.H.

SAWMILL MACHINERY—MODERN DESIGN—most satisfactory to operate. Apply Box 105, Power House.

SAWMILLS—PORTABLE — DOUBLE EDGES; also all kinds sawmill machinery. Apply Box 106, Power House.

WELDING

ELECTRIC AND ACETYLENE WELDING—of broken castings and machine parts, boilers, tanks, and marine repairs. Carter Welding Co., Ltd., 165 Adelaide West, Toronto. Adelaide 2841.

BELTING BARGAIN

ABSOLUTE BELTING BARGAINS—BELTING every description; rubber hose, thresher supplies, tank pumps, pump leather feeds, canvas, McGill auto powers, special reduced prices; for quality and price, you can't beat us. N. Smith, 134 Adelaide west, corner of York, Toronto. When answering this advertisement, please mention this paper. P.F.H.

Every Engineer, Mechanic and Electrical Worker will welcome this new master set. It will answer your problems.

It will help you with your daily work.—A sure source of advancement and higher pay. Complete up-to-date information that is thoroughly and easily explained on every branch of modern engineering and electrical practice.

AUDEL'S ENGINEERS & MECHANICS GUIDES

4750 PAGES · $1 A MONTH
8754 ILLUSTRATIONS · $12 COMPLETE

These Guides tell you all about—

Theory, Practice and Operation of ALL Steam Engines; UNIFLOW and POPPET VALVE ENGINES, and LOCOMOBILES. Locomotive-Marine Engines; Turbines; Rotary Engines --the Indicator --Lubrication --PRACTICAL MANAGEMENT. GAS, GAS ENGINES--*Aeroplanes* and *Aviation*--HOW TO SELECT AN ENGINE. STEAM ENGINE rules and formulae. Steam Boilers; Heat-Combustion; Fuel and Flue Gas Analysis-C02 Recorders-Construction of all types of Boilers,--Mechanical Stockers--Oil Burners--Setting--Chimneys--Mechanical Draught --HOW TO SELECT A BOILER--BOILER DESIGN based on A.S.M.E. BOILER CODE--OPERATION FIRING. Pipes, Fittings--Heating and Ventilation--Refrigeration--Cooling Towers --Condensers--Distilling Apparatus--Elevators--Cranes--Ropes and Cables--Splicing--*Practical Electrical Engineering* as an aid for engineers and electricians in obtaining a license--ready reference index, covering entire field of Modern Electricity.

SHIPPED TO YOU FREE

Not a cent to pay until you see the books. No obligation to pay unless you are satisfied. Send coupon now--today and get this new master set for engineers. Pay only $1 a month.

SEND NO MONEY

THEO. AUDEL & CO.,

RIVAL OF THE CLOUDS
TRADE MARK
Nature's Water Softener
Copyright 1920—The Refinite Co.
For Boiler Feed Water
Refinite makes scale impossible. It takes out the scale-forming lime and magnesia before the water enters the boilers. You save not only fuel, but the trouble, time and expense of washing boilers and replacing tubes.
A coating of scale even 1-50 in. thickness wastes 100 lbs. from every ton of coal fired.
Write for Information and Catalogue.

A Reasonable Saving of 5 to 10%

Should You Expect More?

WE GUARANTEE that with the use of CYCLONE SHAKING AND DUMPING GRATE any grade of hard or soft coal, or screenings of same, can be burned with excellent results both as regards Economy and Capacity; that the total annual expense to the user for coal, interest, depreciation, repairs, damage to boiler, liability of shut-down, etc., will be much less than would be the case with any other type of Grate or Stoker on the market.

The Canadian Steam Boiler Equipment Co., Ltd.
Sole Makers for Canada
20 McGee St. PHONE G. 3660 Toronto, Ont.

Power House

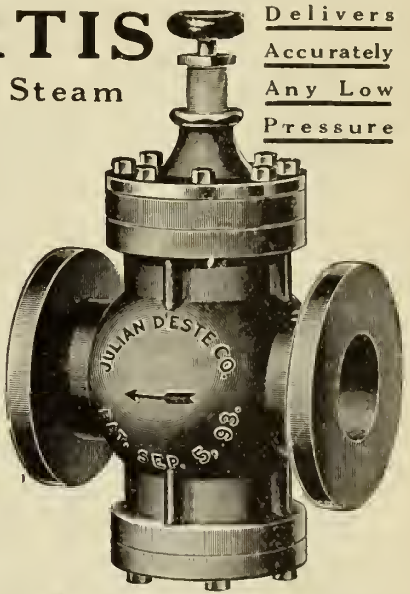
Solves the Problem

It is a dominating factor in maintaining power plant efficiency in equipment and service.

Every issue teems with advertising and editorial matter of a character that will keep YOU right up to the minute in power plant knowledge.

Two Issues per Month
Twenty-four per Year

$2.00 PER YEAR — Every Power Plant employee should read Power House



CURTIS

Improved Steam Pressure Regulator

Delivers Accurately Any Low Pressure

A compact, self-contained Regulator suitable for any boiler pressure. It delivers accurately and uniformly any lower pressure from one to within a few pounds of the initial pressure.

It has no levers, weights or projections; no glands or packing; no drip or leak of steam or water. Use it for efficient service on steam-heating apparatus, slashers, jacket kettles, air or water pumps, pulp mills, etc.

The Improved Steam Pressure Regulator is a lock valve, very simple and sensitive. Send for descriptive pamphlet.

JULIAN D'ESTE COMPANY

Main Office: 26 Canal St., Boston, 14, Mass.

Why Individual Boiler Feed Water Treatment?

Because the Condition of Each Individual Boiler Differs

We have demonstrated it to be the most successful method of freeing boilers of scale and stopping the further formation of scale-forming deposits or incrustations. Corrosion or pitting stopped at once by our scientific process which accomplishes the results desired.

"CLEAN ALL"

Indicates in a few words what the process does.

The demand for our products has steadily increased because the standard of quality has been strictly maintained. We make only one grade, the best that can be produced. Write for prices and further information.

ALLEN BLOCKS *for* **BOILER SETTINGS**

MADE IN CANADA

EVERY Engineer is aware of the decrease in boiler efficiency due to faulty and inferior brickwork around Boiler Headers and Dusting Doors, the inconvenience caused by shutting down of his boilers to make repairs, and the expense and loss of production that accompany each shut-down.

The Allen Header Blocks as illustrated are designed to serve a double purpose to prevent air leaks, one cause of low boiler efficiency, and to protect the header from the hot gases.

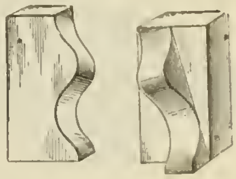
These blocks are conformed to the outline of the Boiler Headers, allowing for their downward expansion, and dispense with the unsatisfactory and expensive method of cutting and fitting each individual brick and setting it in its proper place, from which the boiler vibrations repeatedly shake them loose and result in the shut-down of the boilers, to make the necessary repairs.

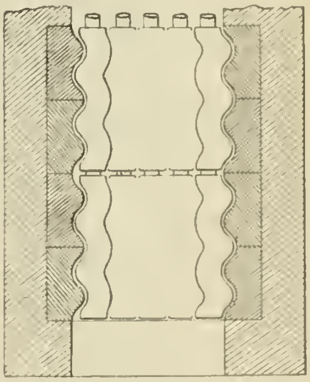
The Allen Dusting Door Blocks (also illustrated) provide an improved brick, which completely insulate the boiler Dusting Doors, wherein the duster openings are provided in integral blocks. These blocks do away with a large number of hand-cut brick, that are ordinarily employed in placing dusting doors. They therefore eliminate the danger of faulty workmanship and consequently shutting down of the boilers to replace the small brick portions that repeatedly fall away.

Both the Allen Header Blocks and the Allen Dusting Door Blocks are guaranteed to last the life of the boiler.

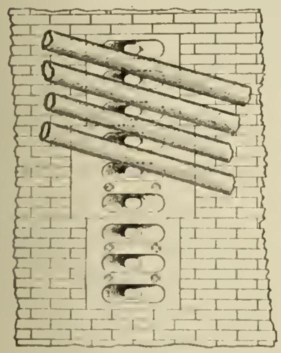
Our thirty (30) years of experience as Boiler Setters is always at your service, both as to new installations and repair work.

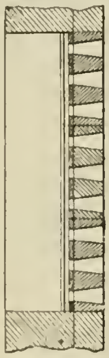
Let us solve all problems dealing with the Settings of your Boilers.





ALLEN HEADER BLOCKS (Patented)





Boiler Settings

For all types of boilers. Settings for Steam and Oil Stills. Stoker Brickwork.

Tycos temperature instruments

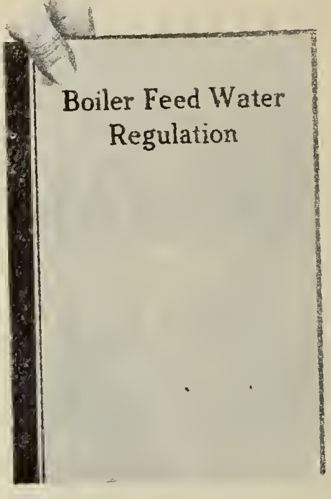
FACILITIES FOR handling the most difficult temperature conditions in the power plant are supplied by *Tycos* Temperature Instruments. The knowledge of just what *Tycos* can do for you when you want anything done and done right will prove invaluable.

This information is given in our catalog part number one. Let us send you this valuable power plant temperature reference book.

Taylor Instrument Companies
110-112 Church St., Tycos Bldg., Toronto
There's a Tycos or Taylor Temperature Instrument for Every Purpose

Are you a STUDENT of power plant economies?

Our experience has been that many of the most succesesful power plant engineers and executives, as you get to know them, turn out to be men who never got over being "students." This leads us to offer, to men in the field, a free copy of this new text book on boiler feed water regulation. Originally prepared for technical students, this little book contains information that every power plant engineer and manager can make use of.



It pictures the first efforts to provide mechanical boiler feed water regulation; tells what objects the first builders of regulators had before them. It explains, step by step, how the different types of boiler feed water regulators developed, giving illustration and description of each.

The man who reads this book—whether he be a student in technical school or the "STUDENT" who is responsible for the economical operation of a power plant—will have a more complete grasp of the subject than he can get otherwise. He will look at any boiler feed regulator with understanding, seeing what is behind it.

Write us for a copy of this new text-book.

Here's the answer to Increased Fuel Costs!

"Burn All"

NONPAREIL SHAKING AND DUMPING GRATES

You'll admit that unless you are getting complete combustion from every pound of fuel you burn, you are not getting full value for the money you spend for fuel. Moreover, you can't hope to get maximum heat value unless your grates are specially designed for this purpose.

NONPAREIL GRATE BARS are demonstrating every day in some of the largest Canadian manufacturing plants that they actually save 10% in fuel expenses. Their 65% air space and 95% underdraft are features that ensure perfect combustion and maximum heat value without waste—even from cheap fuel.

Our 30-day trial (under any kind of boiler) will convince you, too, that NONPAREIL Grates are the logical solution of your increasing fuel costs. No obligation whatever—write us.

THE FILES STOKER

Pays for Itself in One Year

Below is a copy of one of the many letters we have received, telling of the efficiency and economy of the Files Hand-Operated Stoker

Re **FILES HAND STOKERS.**

Gentlemen:—

Frequently we receive letters from manufacturers, asking for information and our experience with the "Files Hand Stokers"—the most economical and efficient system of burning coal with the utmost conservation of labor.

As these inquiries are becoming more and more frequent, our better plan will be to furnish you with a letter to pass on, outlining our experience and satisfaction.

In September, 1920, we placed an order with you for two 150 H.P. Tubular Boilers, specifying our desire to have them equipped with "Files Hand Stokers." This we did on the recommendation of our United States Engineering Department, who had installed "Files Hand Stokers" in some seventeen plants, finding in them a decided saving and advantage over flat or shaking grates.

Speaking for ourselves, we have found them most satisfactory and economical, particularly so in regard to the elimination of smoke, rapid disposal of ash and clinker, thorough cleaning of fires without disturbing the active fire, and in maintaining an even bed of fuel.

We are able to keep a clean fire at all times; we have no cleaning period, for with the "Files Hand Stoker" the grate can be cleaned at peak load. It is only a matter of working one rod on each section, which can be done in less than two minutes.

The better the coal the better the result, but almost any kind of coal that will burn free can be used. With good coal, however, it is an easy matter to procure 150% boiler rating, which in reality is 12½ lbs. evaporation per pound of coal. Generally speaking, evaporation is around 7 or 8 lbs., and often as low as 5 or 6 lbs.

Our Files Hand Stokers have now been installed about two years, during which time they have paid for themselves twice over if we consider the saving in fuel.

And what we have done and are doing with them others can do.

We know they effect a saving; we know they are a convenience; they have proved satisfactory in every particular, and we have no hesitation in recommending them.

Yours very truly,

Messrs. THE WATEROUS ENGINE WORKS CO., LTD.,
Brantford, Canada.

Why not Profit by others Experience?

Waterous

BRANTFORD, ONTARIO, CANADA

D.K. McLAREN'S

Genuine British Oak Tanned

LEATHER BELTING

The Stretch is Taken Out First

The one outstanding feature of D. K. McLaren's Leather Belting is its stretchless quality which, in turn, means the elimination of most of the engineer's troubles.

This stretchless quality is the result of the

Genuine British Oak Tanning Process

used in the manufacture of D. K. MacLaren's Belting. This process, usually considered too expensive for belting manufacture, takes every bit of stretch out of the hide, at the same time adding to its natural toughness and pliability. Incidently, only the **back portions** of specially selected hides are used in D. K. McLaren's Leather Belting.

The Oak Leaf stamped upon every length as your guarantee of "trouble-free" service —look for it.

Flue gases can be reduced 50 degrees by careful firing and clean boiler surfaces

Such is the substantial saving that can be effected by recording and measuring your flue gas temperature with

TRADE MARK
BRISTOL'S
REG. U. S. PAT. OFFICE.
Recording Pyrometers

Of course, the temperature of outgoing gases can be decreased by economizers, or by a change in the baffling — but such changes are costly and the economy depends upon the cost of coal.

The information supplied by Bristol's Pyrometers, as to the temperature of uptake gases leaving the boilers, is of prime importance as an aid to super-efficient plant operation.

Hundreds of Bristol's Pyrometers are recording flue gas temperatures in prominent power plants. Let us tell you more about what they could do in your plant. Our new Catalog O-1401 is waiting for your address.

Jenkins Rapid Action Valve

Can be opened and closed instantly without water hammer

The carefully worked out design and exacting construction of this valve make it absolutely dependable in services where a quick opening water-hammerless valve is needed.

A slight pull of the lever is sufficient to provide full opening and it stays open without the aid of set screws, locking devices or other appliances. Closes instantly with slight pull of lever. Stops water waste. Saves time.

Illustrated literature fully describing this Jenkins Rapid Action Valve will be mailed you on request. Write for it to-day.

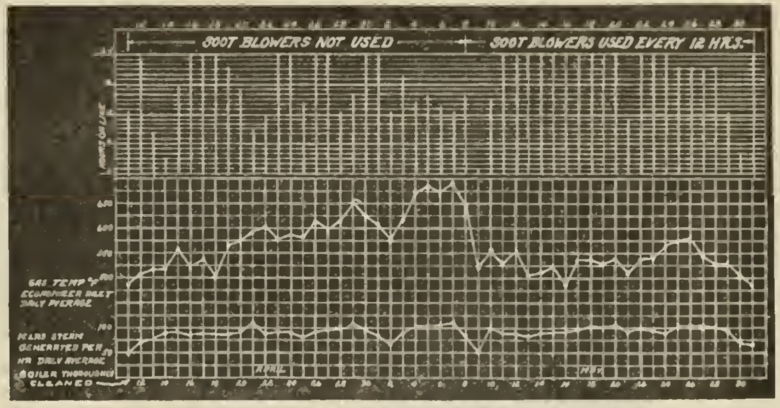
Diamond Soot Blowers

Reduce Flue Gas Temperatures



The chart above covers results of a test made recently by a large central station on a modern 1,000 H.P. horizontal water tube boiler operated at 250 lb. pressure, 200° superheat, and at 200% rating, using bituminous coal handled by underfeed stokers. On April 12th the boiler was put on the line with the tubes, having first been thoroughly cleaned. From this date until May 8th, a period of 26 days, the soot blowers were not used. At the end of this 26-day period, flue gas temperatures had risen from 480° to 690°. The first day the soot blowers were operated the average temperature fell 40°. The next day it fell to 530°. It remained at approximately this average throughout the remaining period of the test, from May 8th to May 30th, during which soot blowers were used every twelve hours.

Obviously any equipment which effects such marked reductions in flue gas temperatures is a first-class investment.

The fuel saved by reducing the flue gas temperatures may be estimated at 1% for each 20 to 30 degrees drop in flue gas temperature, depending upon the amount of excess air in the chimney gases.

On the basis of fuel saving, Diamond soot blowers are one of the best paying investments in the power plant. They pay for themselves many times over during their period of service.

There is a Diamond soot blower for every type of boiler and every boiler needs one. Send data regarding your boiler equipment and write for full information. Ask for Bulletin 287.

Diamond Specialty Ltd. - Windsor, Ont.

De Laval Gasoline Engine Driven Pumps for Fire Protection at Barrie, Ont.

Barrie uses two electric motor driven De Laval pumps, while a third, an 8 in. two-stage pump, is driven by a Sterling gasoline engine. The latter, which has a capacity of 1800 gal. per min. against 275 ft. head when running at 1400 r.p.m., can easily be started on a moment's notice, and provides fire protection in the event of failure of the electric current supply. De Laval centrifugal pumps are ideally adapted for gasoline engine drive because of their high efficiency, low starting torque and power limiting characteristic.

The horizontally split casing, with suction and discharge connections in the lower or main part of the casing, renders all internal parts at once accessible upon lifting the casing cover. There are no diffusion rings to become damaged or rusted. All parts are made to limit gages on an interchangeable basis, and parts subject to wear, such as shaft protecting sleeves and bearings, are easily replaced. The efficiency is guaranteed and is demonstrated by test at the factory.

If interested in pumping, whether by steam, electricity, water power or internal combustion engine, read our book W-100, "Ten Years' Progress in Water Works Pumps."

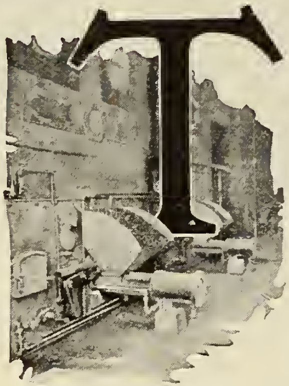
Now an entirely under-fed side cleaning stoker



THE arrows below are the symbol of a great development in mechanical stoking. They trace the path of fuel travel of a stoker that embodies a new basic design—the *lateral retort* principle.

Briefly summarized the advantages of the *lateral retort* design are:

The multiple retort effect. Coal is underfed to the *lateral retorts* as well as to the main or central retort. It is not overfed from the main retort onto side grates as in other stokers employing side dump plates. Consequently, the principle has made possible for the first time; **a truly underfeed side-cleaning stoker.**

Heavy overload capacity. The *lateral retort* design provides a large reserve fuel capacity for meeting overload demands.

Low maintenance. The *lateral retort* construction also permits a simple, rugged construction; only two simple steam cylinders and a few moving parts buried deep in the green coal where they cannot burn out. The simple balanced dump plates—of the type that has proved so successful in the Jones "A-C" stoker type — insure an additional saving in maintenance.

Low initial and installation cost. The extreme simplicity permits a moderate first cost, and the side dump construction does away with basement ash pits and expensive excavation. For this reason the "*Lateral Retort*" Stoker is adaptable to any conditions in existing plants.

The construction and advantages of this stoker are thoroughly covered by a new catalogue. Ask for it.

From Asbestos Rock to Stuffing Box Entirely Heat Resisting.

Why Does "PALMETTO"

give longer service than other rod packings, even under high pressure superheated steam and compressed air? It is simply because it is made of an unusually high grade of Canadian asbestos of such long fibre that the addition of cotton as a binding substance is not necessary.

"Palmetto" always gives the same uniformly long service, no matter how long in stock, and no matter how trying the climate.

"Palmetto" is frictionless

because it has graphite grease lubricant forced hot under pressure into each single strand before braiding.

Let us send you working samples to test under your own conditions no charge.

REFRIGERATION DEPARTMENT

LINDE

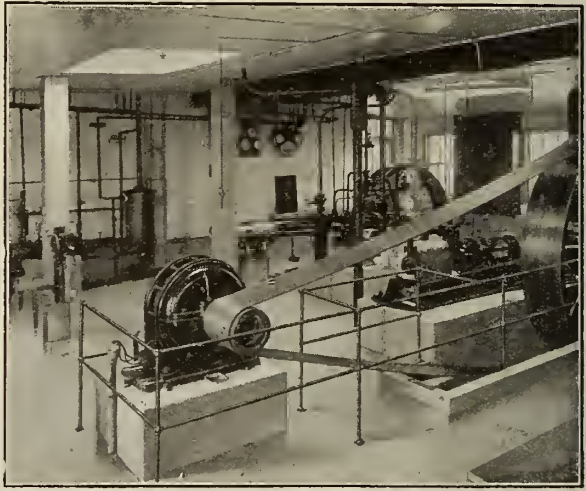
REFRIGERATING AND ICE MAKING MACHINERY

Made in Canada

For Refrigerating and Ice Plants.
Large and Small.

Mechanical refrigeration scientifically applied yields increased returns to the user.

Linde Refrigerating and Ice Making Machinery offer every improvement and convenience. Our new vertical enclosed type machines are designed for plants from 1 to 30 tons. Then for demands calling for loads up to 300 tons, our horizontal frame type is guaranteed to give better service than any other equipment on the market.



This 100-ton plant was designed by our engineers These men are at your service. Designs, specifications and estimates upon request.

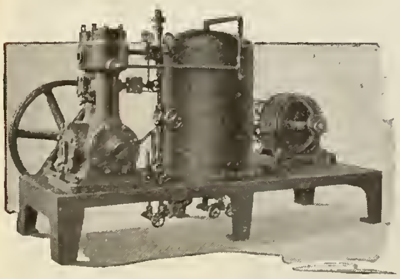
VILTER

ICE MAKING AND REFRIGERATING MACHINERY



A self contained unit built in capacities up to four tons refrigeration. Bulletin No. 29-R describing this and larger size equipments will be promptly forwarded on request.

THE VILTER MANUFACTURING COMPANY
Established 1867
242 BEECHER ST., MILWAUKEE, WIS.
Branch Office: 68 Higgins Ave., Winnipeg, Man., Canada

Use Nonpareil Cork Fitting Covers

When you put Nonpareil Cork Covering on brine and ammonia lines, **always** use Nonpareil Cork Fitting Covers on all fittings. Never try to cheapen the job by covering fittings with a different material—plastic or wrapped. The insulation must be continuous and identical along the entire line. Otherwise frost is sure to form, and, forcing its way back along the line, ultimately destroy the covering.

Nonpareil Cork Covering

For Brine and Ammonia Lines

is made for all pipe sizes, and Nonpareil Cork Fitting Covers for all fittings—standard or special—screwed or flanged. For the sizes commonly used, there are molded jackets in two sections. They fit up to or over the pipe covering, making an air-tight joint with no voids and eliminating all possibility of condensation and frost. Everything needed for proper application comes with Nonpareil Cork Covering and Fitting Covers. There are no extras to buy.

Improperly covered fittings are "weak spots" on insulated lines. Make your lines a unit from end to end—Nonpareil Cork Covering on the pipes and Nonpareil Cork Fitting Covers on all fittings.

Further information will be supplied promptly on request.
Write for a sample and literature—there is no charge.

When Overhauling

——Dependable Ammonia Valves, Fittings and Auxiliary Equipment are of paramount importance.

YORK Valves and Fittings of every size, style and type are made of either malleable iron, drop forging, or air furnace iron, tested and inspected at every stage of manufacture and guaranteed to give satisfaction under all usual working conditions.

Every heat of metal going into York Valves and Fittings is tested physically, analyzed chemically and inspected metallographically. All materials entering into the construction of York Products are subjected to similar rigid tests, insuring a uniform high grade product.

YORK Auxiliary Apparatus, such as Ammonia Drier-Cooler-Purifiers, Ammonia Distillers, Condensers, Receivers, Automatic Can Dumps and Fillers, Hoists, etc., all help materially in increasing the efficiency of the plant and the profits of its owner.

Our Engineers will assist you in selecting the apparatus best suited for your purpose, and in solving your ice making and refrigerating problems. Write us today.

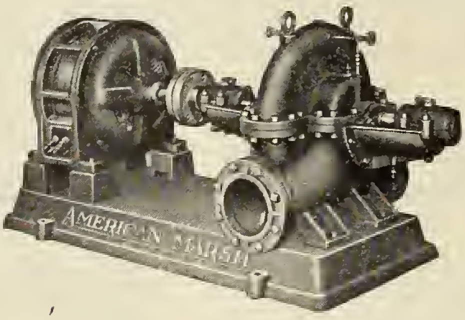
AMERICAN-MARSH PUMPS

Centrifugal and Direct Acting



Designed for use in power plants where absolute reliability and high efficiency are essential. For over thirty-five years American-Marsh Pumps have been recognized as standard throughout the Dominion. There are over 160,000 in successful operation.

The sturdy rugged construction and heavy cast bronze fittings insure long life and a minimum repair expense.

American-Marsh Centrifugal Pumps are built with the same painstaking care that characterizes the construction of the direct acting line.

The Line includes :

- Boiler Feed Pumps
- Air Compressors
- Deep Well Engines
- Centrifugal Pumps
- Jet Condensers
- Vacuum Pumps
- Condensation Pumps
- Sump Pumps

May we send you our general Catalog ?

DIRECT-CONNECTED OIL ENGINE AMMONIA COMPRESSORS

For plants requiring approximately 30 tons of ice or 50 tons refrigeration per day

The Price Oil Engine, which constitutes the power end of Type POC-A Ammonia Compressors, has a guaranteed fuel consumption of 0.45 lbs. per brake horse power hour at full and ¾ loads. Fuel injection is direct, without the use of compressed air; ignition is by heat of compression only.

The double-acting ammonia cylinder is fitted with I-R Plate Valves, all discharge valves being located at the bottom of the cylinder. Gas passages are unrestricted and valve areas are unusually large, guaranteeing efficient compression.

This direct-connected unit is especially suited for carrying the reduced winter load of plants requiring large capacity during other seasons. The ease of starting and elimination of standby losses make this oil engine-ammonia compressor ideal for standby purposes.

Ice and Refrigeration Plant Equipment

AMMONIA COMPRESSORS

Built for either single or two-stage operation, and for belt, steam, oil engine or direct connected electrical motor drive.

AIR COMPRESSORS

Can be furnished in all sizes and for any commercial discharge pressure. These units are particularly suitable for supplying air for agitation. Air Lift Pumping or for general power purposes. Any type of drive.

AIR HOISTS

Built in five sizes for from 1,000 to 10,000 pounds capacity. These hoists are extensively used for lifting ice cans and for general hoisting work. They are easy to move about the plant, and simple to operate.

PNEUMATIC TOOLS

A complete line of riveters, drills, grinders, etc., for erection, assembly and repair work.

CAMERON PUMPS

For pumping brine, water and other liquids. These can be furnished in direct-acting type for steam or compressed air drive, or in centrifugal type for belt, motor, steam, oil or gas engine drive.

PRICE OIL ENGINES

Of the direct-injection, four-cycle type. Horizontal, single cylinder types of 50 and 100 H.P., and vertical, multi-cylinder types from 105 to 1,000 H.P. AC-2

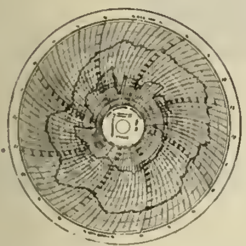
Are Your Feed Water Temperatures High?



Foxboro two-pen record of economizer water inlet and outlet temperatures. In this plant oil burning boilers are used, which accounts for the low range of temperature. The double record is an exceedingly effective check on economizer efficiency.

Careless or inefficient use of exhaust steam or accumulation of soot and scale in feed water heaters and economizers quickly shows up in increased fuel consumption.

Complete knowledge of feed water temperature is the first step toward the elimination of this large source of fuel waste.

Foxboro Recording Thermometers on your feed water heater outlets and economizer inlets and outlets give you accurate, continuous information about the operation of your feed water equipment.

The permanent dependability of Foxboro Recorders and their many exclusive design elements which insure accuracy and convenience make them the logical choice for this important service.

Let us show you why power plant engineers consider the Foxboro Recorder "The Compass of Industry."

Write to Dept. CF.

Foxboro feed water temperature chart, produced at one of the largest power plants in the country. The high temperature and small variation mean economy. A few days previously, when the instrument was installed, low temperature and wide fluctuations were revealed. The charts guided regulation and led to a saving of thousands of dollars.

An "Extension"-Style Thermometer

**Like an "Extension" 'phone—
Mercury Bulb in one place,
Indicating Dial in another.**

THERE, in a nut-shell, you have the advantages of the Columbia Reform Thermometer, for use at any dark or scorching-hot or inaccessible point where temperature must be known.

Instead of a hard-to-read mercury *tube*, you have an easy-to-read *Dial.*

And instead of the dial being installed at the point where the temperature is to be taken, it can be installed on the wall, on the gauge board in engine room, or *anywhere* within a reasonable distance from point of application that is most convenient.

Columbia "Reform" Dial Thermometers

do away with all the old difficulties and temper-trying inconvenience of taking temperature at points difficult of access — hence the name Columbia "Reform" Thermometer.

Columbia Reform Thermometers are sensitive to the slightest temperature variation and are thoroughly accurate and dependable. They are mercury-actuated throughout.

This thermometer consists of a steel bulb, steel capillary tube and steel coil spring, all filled with mercury. The connecting tube can be supplied any reasonable length and the bulb is furnished for all applications.

Can be furnished for any range of temperature up to 1000° F.

Ask for Catalog G-33.

Refrigeration a Mighty Factor in Economic Life

Canadian Field Extending Daily With Result that Power Plant Engineers Find it Intruding to Such an Extent as to Demand of Them a Sound Working Knowledge of the Cycle of Operations

FROM the time of its first application to the primary industries of Canada as in the chilling for export of butter, eggs, cheese, etc., its application in the field of purely local requirements as in the manufacture of ice cream, ice plants, dairies, hotels, clubs, butchers' shops, etc., mechanical refrigeration has been a mighty factor in our economic life.

Its field is extending and the number of installations is rapidly increasing, with the result that a number of engineers and others who formerly gave but little thought to the subject, find it today intruding under their notice to such an extent as to demand of them a reasonably sound working knowledge of the cycle of operations.

Temperature

The terms hot and cold are purely relative. They express a condition, viz., the temperature condition of a body, substance or place in relation to some other body, substance or place. Speaking non-techincally, a body having a temperature of 120 deg. F. is considered hot while 60 deg. F. is considered cold, because the former is about as hot as the hand can stand and, in this manner of speaking, the temperature of the human body is the basis for comparison.

Similarily, boiling water at 212 deg. F. is considered hot, and melting ice at 32 deg. F. cold—relatively to the human body.

On the other hand, boiling water is cold in relation to the flame which heats it, and melting ice is hot in relation to say anhydrous ammonia vaporising at—29 deg. F. under atmospheric pressure.

Considering the temperature range covered by these examples, the necessity for an instrument to correctly measure degrees of temperature is at once apparent; and a little reflection will serve to show how seriously handicapped were the early scientific investigators prior to the invention of the thermometer—without which the discussion of heat problems would be impossible.

With a proper appreciation of the importance of the thermometer, particularly in refrigerating work, will come a corresponding realization of the necessity for its correctness and reliability. Careful calibration and the application of the corrections thus obtained to observed temperature readings are essential if accurate results are to be obtained.

Whatever the engineer finds to do that is helpful should be done with all his might. There is no dishonorable work except that which is done without purpose. Labor that is not essential to human welfare is uneconomic. Men who do not fit in at serviceable jobs in Canada's industrial machinery are parasites. Hard work brings forth services, secures promotion, and develops economic power. It augments the earnings of the engineer and the capitalist alike, and promotes the happiness of the whole industrial army.

In measuring degrees of temperature, the thermometer makes possible the determination of heat quantities, which are expressed in terms of British thermal units, one B.t.u. being the quantity of heat required to raise the temperature of 1 lb. of water 1 deg. F. If, therefore, 5 lb. of water be raised through 20 deg. F., 100 B.t.u. will have been imparted to it, but its weight remains unchanged.

Heat is intangible, something like liquids and solids or manipulated like certain substances, but which, nevertheless, can be measured and handled in quite as positive though a different manner.

Cold does not exist; it is merely a state or condition caused by the removal of heat, which in theory may be intensified until the point of absolute zero is reached at—460 deg. F., at which point heat ceases to exist.

The second law of thermodynamics states that heat cannot of itself, i.e., without the application of external work, pass from a colder to a warmer body. Its natural tendency is to pass or flow from a higher to a lower temperature level.

An analogy is to be found in the case of water, which will readily gravitate from a higher to a lower level but must be pumped or lifted from a lower to a higher level. A helpful mental attitude is, therefore, to consider heat as something very real, something which can be moved about from place to place, abstracted from one body and imparted to another, converted into useful work or completely rejected if so desired.

Refrigerating Medium

In refrigerating work, the heat removed from the goods (or from the water in the case of ice making), is subsequently rejected to the condensing water and ultimately, if a water cooling tower is used, to the atmosphere.

Since the temperature of the condensing water during the summer months may be as high, or even higher than 80 deg. F., some low temperature medium or working substance must be introduced to first receive the heat at the lower temperature of the refrigerator; and mechanical means then employed to dispose at the higher temperature level of the condenser, of the heat absorbed by it.

Apparatus Required

Should a very inexpensive medium be discovered, so cheap to produce that it could be discarded with the heat absorbed by it, all the apparatus necessary to cool a tank of water, would be a pipe coil immersed therein and an expansion valve for regulating the flow of the substance through the coil. Its intrinsic energy would need to be very high otherwise the enormous quantities required would place it outside the realm of practicability. Such a working substance would be used as a fuel and, in this respect, would bear much the same relationship to the refrigerating plant as does oil to the internal combustion engine. It would be exhausted to the atmosphere after use.

Unfortunately, however, all refrigerating media are expensive, consequently it becomes necessary to provide apparatus for suitably rejecting the absorbed heat from the system so that the working substance may be again capable of performing useful work of refrigeration. Two additional pieces of apparatus are required to perform this function, viz., a compressor and a condenser. The system becomes then a closed one, the cycle of operations continuous and the refrigerating plant found to consist of the following four pieces of apparatus,—1. A refrigerator or evaporator; 2. A compressor or gas pump; 3 A condensor or liquifier; 4. An expansion or regulating valve.

Cycle of Operations

As the refrigerating plant comprises four fundamental pieces of apparatus, so the refrigerant or working medium undergoes four changes in one complete cycle of operations. An analogy is to be found in the case of the heat engine in which heat is received by the steam from the furnace at the higher temperature level of the boiler, portion of it transformed into work in the engine cylinder, the remainder rejected at the lower temperature level of the condenser and finally the condensate heated to the temperature of the boiler thus completing the four stages of the cycle.

In the refrigerating system the foregoing cycle is reversed, heat being received by the ammonia at the lower temperature level of the refrigerator, external work then done upon the medium in the compressor, the heat rejected to the cooling water at the higher temperature level of the condenser and finally the ammonia cooled to the temperature of the refrigerator where its condition is now in every respect the same as at the beginning of the operations.

These four stages of the ammonia compression refrigerating system will now be examined, to facilitate which it will be assumed that the temperature of the refrigerator is 5 deg. F. and that of the condenser 86 deg. F., these being the temperature levels adopted by the American Society of Refrigerating Engineers as a standard basis for rating the capacities of refrigerating machines.

Fourth Stage

It will be advantageous to examine firstly, the final stage of the cycle, representing the passage of the ammonia through the expansion valve.

Under practical operating conditions, the refrigerant (which reaches the valve as liquid) undergoes a throttling process at the expansion valve without the addition or substraction of heat, its heat content remaining unchanged. Its temperature is reduced from that of the condenser to the temperature of the refrigerator by the vaporisation of portion of the refrigerant, sensible heat being taken from the ammonia and rendered latent during the process, a drop in temperature resulting. This change in the state of the medium at the expansion valve is not peculiar to the refrigerating system. The same phenomena maintain at—for example, the blow-off or trial cocks of a steam boiler.

When any such under-water fitting is opened, the pressure on water passing the valve is reduced from that of the boiler, say 180 lb. gauge, to the pressure of the atmosphere, viz., zero gauge,—the corresponding drop in temperature from 379 deg. F. to 212 deg. F. being brought about by vaporisation of portion of the water. Consequently steam and water are together observed to pass to the atmosphere. The liquid is cooled at the expense of effective work of refrigeration. The amount evaporated during the change from 86 deg. F. to 5 deg. F. can be shown to be 16 per cent. The remainder, 84 per cent. is liquid at 5 deg. F., and is available for performing useful work in the refrigerator.

First Stage

The first stage represents useful work in the refrigerator. The refrigerator or evaporator may take the form of pipe coils immersed in a tank of water or brine, piping placed on the walls and ceilings of freezing rooms, a battery of coils over which air from the coil rooms is circulated by means of a fan, etc., etc., as the case may be.

If your plant is standard in every respect—if you have worked hard to build up efficiency to a point that reflects credit on yourself—surely you do not intend to rest on your laurels now. Somewhere in Canada there is probably a plant that is meeting the same conditions as yours—at a lower cost.

And there you will find a man who is not yet satisfied—a man who is still striving for a little more—a man who, although already high on the peak where the grade is steepest and the effort greatest, is still pushing upward.

Referring again to the heat engine cycle, the refrigerator is analogous to the steam boiler. In the latter, the quantity of steam generated per unit of time is proportional to the heating surface. Similarily, the quantity of ammonia vaporised in the refrigerator and consequently the amount of useful work performed, is, other things being equal, proportional to the evaporating or heating surface. The ammonia here undergoes an isothermal change since it is carried out at constant temperature; the quantity of heat absorbed being equal to 474.3 B.tu. per lb.

Second Stage

The second stage represents the work of compression, the object being to bring about such a state or condition of the working substance that the heat absorbed by it in the refrigerator may, by condensation, be rejected to the cooling water. The point should here be noted that the standard condensing temperature of 86 deg. F. contemplates a mean cooling water temperature of approximately 71 deg. F. (ranging from 65 initial to 77 final), the temperature difference of 15 deg. thus insuring a satisfactory rapid transfer of heat from the working substance to the water. Now, increase of pressure increases the dew-point (or temperature at which condensation takes place) of a liquifiable vapor; consequently since a condensing temperature of 86 deg. F. is demanded, it is found from tables of properties of saturated ammonia, that a corresponding pressure of 155 lb. gauge must be applied.

Anyone who has had occasion to inflate a pneumatic tire by means of a hand pump knows, firstly, that external work must be expended to compress the air and, secondly, that the work of compression generates heat.

Similarly, in the referating system, heat is imparted to the ammonia and its temperature increased accordingly when external work is applied. In what is known as the dry compression system (which is the system under review), the whole of the liquid which passed the expansion valve is assumed to be vaporised in the refrigerator, so that only dry and saturated vapor reaches the compressor. Compression proceeds adiabatically, i.e., at constant eutropy, or, without gain of heat other than that due to the external work applied, and without loss, the compressor walls being assumed perfect non-conductors of heat.

In such a cycle, the work done per lb. of ammonia is the difference in heat content at the beginning and end of compression. For the standard temperature levels of 5 deg. F. and 86 deg. F., where the refrigerant enters the compressor at 19.6 lb. gauge pressure and is discharged against a pressure of 155 lb. gauge, it can be shown that the heat content of each lb. of ammonia circulated is increased by 99.3 B.t.u. This quantity of 99.3 B.t.u. is the heat equivalent of the mechanical work expended in compression.

Third Stage

The third stage represents the work of condensation. The type of condenser familiar to most readers is, doubtless, the atmospheric type consisting of wrought iron pipe coils over which the cooling water is showered. The gas leaving the compressor is superheated, its temperature being 208.4 deg. F = 122.4 deg. of superheat. This sensible heat is first removed by the cooling water until the condensing temperature of 86 deg. F. is reached, after which the latent heat is removed at constant temperature and the refrigerant returns again to the expansion valve as liquid thus completing the cycle of operations.

The theoretical heat balance in a closed cycle of operations states, in broad terms, that the heat taken up by the working substance must be equal to the heat rejected from it. In the

(Continued on page 40)

Ash Handling—The Step-child of the Power Plant

Although Experts Admit Coal-handling Often is Featured as the Big Problem—Ash Disposal and the Cleaning of Fires Are of Practically Equal Importance in Cutting Costs

ON ONE point all authorities in Canada who have made a thorough study of ash disposal methods and costs are in full accord. They agree that ash handling is the stepchild of the power plant, that coal-handling is featured as the big problem while ash disposal and the cleaning of fires, actually of practically equal importance, are slighted.

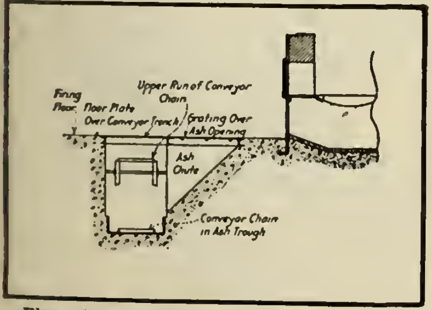
A recent paper by John Hunter and Alfred Cotton gives the ash disposal problem the attention it deserves:

"Ash handling is just as important as coal handling. It is a simpler problem only to the extent that there is less ash than coal, but the coal disappears while the ash accumulates. The ash must be got rid of or the plant will be put out of commission.

"Except that there are several standardized types of conveyors, classification of methods of ash handling is not convenient and would serve no useful purpose. Each problem must be considered entirely according to its particular circumstances. The methods of offering the ash in the first place, the general conditions to be met, and the final disposition are all so varied and the possible combinations of each are so numerous that each installation is different from others in some respects.

Rudimentary Methods

"No doubt the most rudimentary method is that in which the ashes are hoed out of the fire doors and the ashpits onto the firing floor and are shoveled into wheelbarrows which are dumped outside the boiler room, either to fill up depressions or to be carted away. In some cases, the ashes are shoveled into industrial railway cars, which are then pushed to the dumping point. In some existing plants, a basement is out of the question, and even if a change were made to stoker firing, the ashes would still have to be hoed out of the ashpit. But the wheelbarrow can be replaced by either a mechanical or air conveyor.



Firing Floor
Floor Plate Over Conveyor Trench
Upper Run of Conveyor Chain
Grating Over Ash Opening
Ash Chute
Conveyor Chain in Ash Trough

Fig. 1A—Block chain conveyor in trench.

"Figure 1A is a cross-section of a block-chain conveyor running in a trench under the firing floor. The ashes es are hoed on to the grating, through which they fall down the chute to the bottom of the trench. They are then drawn along by the chain, discharging into a bucket elevator as illustrated in Fig. 1B or onto an inclined chain conveyor carrying the ash into an elevated storage hopper.

Sufficient Supply Rate

"Where there is a plentiful supply of water, a flume may be carried along under the firing floor and the ashes raked into it through the openings. This is a very simple method, but it is seldom that a natural water supply and sufficient fall from the plant are available adequately to dispose of the ashes.

"When the boiler room is considerably below the ground level the problem is more complicated. In such cases there will seldom be a basement below the boiler room, partly on account of the expense of further excavation, and often because of difficulties with building foundations and water. Good examples are the boiler rooms of office buildings and hotels, where the boilers are generally a considerable distance below the street level and the building is closely surrounded by streets and other buildings. Whatever the final disposition may be, the ashes are invariably removed from the vicinity in motor or horse-drawn trucks. Here the important consideration is principally that of hoisting the ashes from the boiler room to the street. The crudest method is to load the ashes into ash cans and hoist them by hand-operated block and tackle to the street. This entails high labor cost.

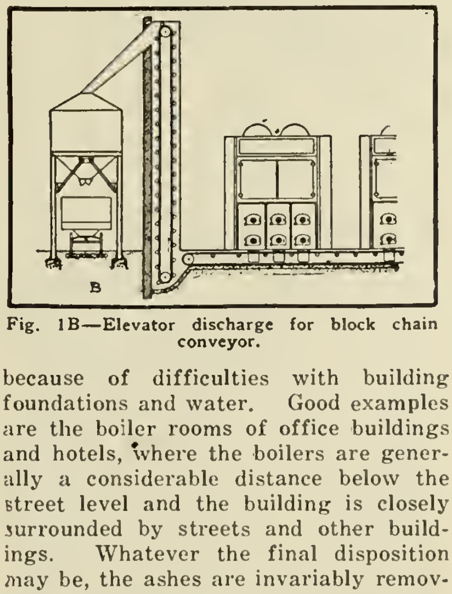


Fig. 1B—Elevator discharge for block chain conveyor.

Noise Hampers System

"In some instances, the air conveyor (the so-called steam-jet conveyor) has been used advantageously in hospitals, hotels and office buildings in crowded parts of cities, but it is not always applicable. Unless certain precautions are observed, such as connecting the air discharge into the chimney, the noise may entirely prevent the use of the system.

"Another method is the 'post box' elevator. The ashes are stored in the boiler room until the arrival of the ash truck. The elevator, which is of the bucket type, has a telescopic housing which is pushed up through the sidewalk opening and the chute extended to discharge into the truck. When the truck is filled and the elevator stopped, it is withdrawn below the sidewalk and the cover closed over the opening. The casing of the elevator is telescopic to allow of its retraction below the sidewalk, and the bucket chain is so designed as to allow the slack to pile up in an orderly manner at the bottom without becoming entangled.

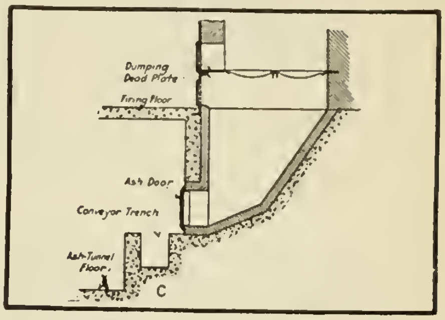

Fig. 1C—Conveyor trench at basement ashpit door.

"Where conditions allow, an ash storage hopper may be constructed within the building and a closed ash chute temporarily extended over the sidewalk to the ash truck. The storage hopper may receive ashes from a bucket car and whip hoist, a bucket elevator, or an air conveyor. It is not often that this method can be employed. The purpose of the building may entirely prevent the use of such a hopper, and the temporary extension of the ash chute over the sidewalk would not be permitted in the better or more crowded streets.

Hopper Ashpit Saving

"As the first operation where labor can obviously be saved is in avoiding hoeing and shoveling ashes at the outset, this leads naturally to a consideration of the hopper ashpit. The hopper ashpit is regular practice in the modern plant. Its size and general design will depend primarily upon the manner in which the ashes flow into it, the method of removal, and also upon the system of draft. The design begins at the top to suit the stoker.

"In hand-fired, forced-draft anthracite plants the top of the hopper will conform to the whole grate area. With stationary grates fine ash is falling constantly over the whole area. As the fires are hand-cleaned, a dumping deadplate will keep the ash away from the firing floor and allow it to fall directly into the hopper, the forced draft being temporarily shut off. With dumping grates the ash will also fall from most of the grate surface. The ashpit will most probably be a storage hopper, which will be emptied at intervals with the forced drafts shut off. Large capacity is necessary because of the high percentage of ash in this fuel. The discharge door must be airtight to avoid increasing the cost of generating the forced draft and the possible reduction of ashpit pressure's lowering the boiler capacity. If it can be dumped directly into railroad cars, the basement being deep enough for this purpose, the hopper can be quickly dumped through bottom doors.

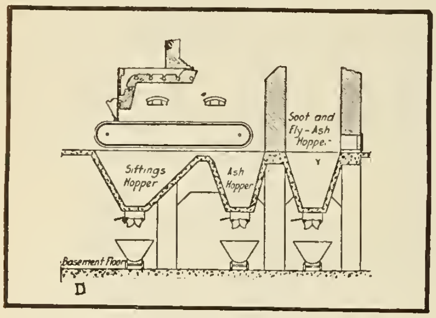

Fig. 1D—Chain grate with ash, siftings and soot hoppers.

Value of Conveyors

"Where conveyors are installed it is usual to use a side door and work the ashes out gradually into the conveyor to avoid choking it, as would happen with a straight dump. Figure 1C illustrates a layout of this kind. The conveyor will occupy the trench in front of the ash door. It may be mechanical, bucket or chain, or air or water, and is therefore shown schematically only.

"With forward-travel underfeed stokers, chain-grate stokers, front-feed inclined stokers, and others the ashes are dumped at the rear of the furnace and the top of the hopper will be the width of the fire but of small dimension from front to rear to accord with the stoker dump. This reduces the capacity for storage.

"With chain-grate stokers a hopper should also be provided for fine coal which sifts through the grates before ignition. Such an arrangement is shown in Fig. 1D. This coal is dumped into some means of conveyance to be returned to the stoker coal hoppers.

"Side-travel underfeed stokers dump at each side of the wind box for the whole depth of the fire. Hopper ashpits for this type of stoker may therefore have greater storage capacity since the top of the hopper extends to the front of the boiler. Fig. 1E illustrates an ashpit of this kind.

"In discussing the amount of storage required, it will be noticed that there are frequently two places where the ash is stored; in the ashpit and in the elevated ashbin, if there is one. In some instances small capacity may be sufficient, owing to storage being taken care of outside the ashpit. The method of conveyance from the ashpit will have considerable bearing on the ashpit capacity necessary. But 24 hours' capacity should usually be provided in case of breakdown of conveyors, etc. Consequently some of the attributes of different methods of ashpit conveyance which bear on ashpit capacity should be mentioned here. The largest ashpit capacity will be requisite with conveying systems which are operated intermittently. These will include instances where ashpits are dumped into industrial railroad cars or into conveyors which might be choked by the direct dumping of an accumulation containing large clinkers and therefore need hand feeding or at least manual attention. Where a continuous-conveyor system is used the ashpit may be much smaller, and sometimes the ashpit becomes simply a funnel or chute to guide the ashes into the conveyor.

"Since the required capacity depends upon the amount of ash that accumulates between emptyings, it is controlled by the rate of firing and the percentage of ash in the coal. Multiplying the weight of coal burned between dumpings by the percentage of ash and allowing 40 lb. per cu. ft. gives the storage space required. Allowance must be made for unburned coal coming in with the ash, for neglect to empty regularly, for possible increase in the load and consequently in the rate of combustion, and for possible change to dirtier coal. The careful engineer will make the capacity of his ashpits perhaps 50 per cent. greater than the calculations show, or even more. Also, sufficient space should be left above the top of the ashes in order to prevent burning and breakage of stoker mechanism.

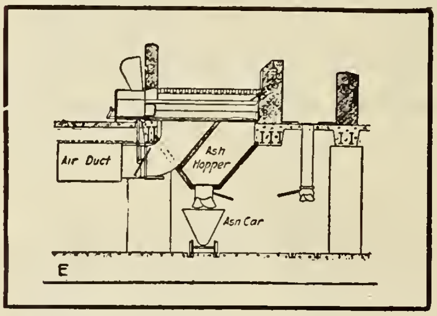

Fig. 1E—Hopper ashpit for side-travel underfeed stoker.

Hopper-Ashpit Design

"Ash hopper sides should slope at not less than 45 deg. in any case, and a minimum of 50 deg. with the horizontal is preferable. If one side is vertical the opposite side may have the minimum slope; but where two opposite sides slope, neither should slope less than about 55 deg. If the slope is too small, arching of the ash is likely to occur and this will increase operating costs owing to the frequent necessity of encouraging the flow by breaking away the ash with bars poked up through the discharge doors. Where the width of the hopper would necessitate too great height to get these required slopes, the ashpit may easily be divided so as to have a number of discharge openings.

"If a very small slope is used so as to get large capacity, access doors should be provided at the top of the slope so that the ashes may be pushed to the dump doors with a minimum of labor, and ample space should be left so that long ash tools can be wielded with ease.

Discharge Openings

"Large discharge openings should be used, though their size depends to some extent upon the method of firing. When small anthracite is burned with sufficient steam in the combustion air, no clinkers are formed and the ash is in small pieces and easily dumped. Modern intensive firing of bituminous coal tends to cause the formation of large clinkers, and the openings should be large enough to pass these without having to break them into smaller pieces to allow dumping. In earlier installations, door openings about 18 in. square and even less were common, while modern practice required 30 to 36 in. as a minimum, with many instances of clear openings 5 ft. square.

"In some instances the discharge door is in one of the sides of the hopper as in Fig. 1C and the attendant hoes out the ashes either into cars or conveyor. Whenever it can be adopted, however, the bottom discharge is undoubtedly the least costly in labor and well repays the added expense of the greater height of basement needed.

"Height of the bottom of the hopper above the basement floor depends upon the systems of conveyance adopted. It is greatest where standard railroad cars are used, about 8 or 9 ft. to clear the cars, and about 17 to 18 ft. if a locomotive must pass under. With industrial cars 5 or 6 ft. is sufficient, though a clear headroom of 6 ft. 6 in. to 7 ft. is preferable. With some conveyors it may be much less, but in any case there should always be sufficient vertical space to allow a bar to be pushed up into the hopper to clear away any ob-

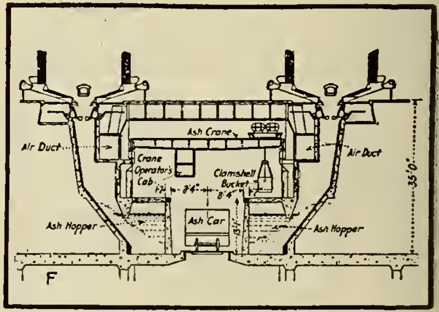

Fig. 1F—Double water-sealed ashpit layout for large plants.

struction. In designing new plants ample headroom should always be provided.

Ash Quenching Water

"Where storage takes place in the ashpit, water spray pipes should be provided for quenching the ashes. These pipes should be near the top and sheltered from the incoming ash. Or a substantial spray ring may be used. Many prefer to make the hopper sufficiently large for the ashes to remain long enough to cool naturally. By allowing some ash to remain when dumping, for the new hot ash to fall on, the doors and lining are protected and the ash gradually cools without the use of water. If too much water is used, it will leak from the dump doors and flow about the basement; and as it contains much fine ash in suspension, it will clog sewers and necessitate cleaning them frequently.

"Hopper-ashpits will usually be provided with doors to retain the ash and prevent the passage of air, and to allow of the ash being dumped or hoed out at intervals as desired. With hand firing and natural draft the doors need not be airtight so far as draft is concerned; but with chain grates and with closed ashpit forced draft the doors should be tight to avoid loss of air pressure and waste of blower power.

Excess Air Dangers

"Inleakage of air may reduce boiler efficiency in some cases by excess air passing the fire through the stoker ash dump; and when forced-draft stokers are heavily loaded, gas may escape through the dumping doors. Where much combustible gets into the ashpit, either through carelessness or imperfections in stoker design, leakage of air through ill-fitting dump door often causes sufficiently rapidly combustion in the ashpit to result in damage to grates, hopper structure, or dumping doors.

"Airtight ash doors are therefore highly desirable in almost all cases.

"There are several cases in which the dump openings may be sealed. The doors and faces may be machined, or the frame may be provided with a groove packed with asbestos rope, while the door has a rib or tongue which is squeezed into the asbestos packing by a crossbar and screw spanning the door. The latter method has been used with satisfaction in vertical doors like that of Fig. 1C. The door and frame may sometimes be left unfinished with sufficiently well-fitting smooth-faced castings that will prevent much ingress of air. The doors should usually be lined with firebrick to prevent warping due to hot ashes lying on them soon after dumping.

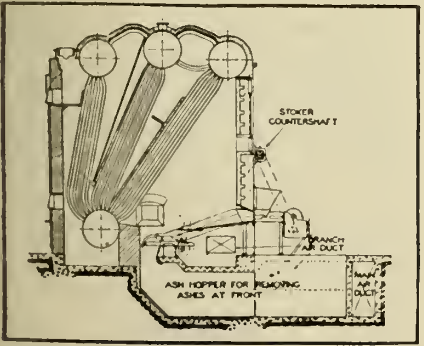

Fig. 1H—Ashes removed at front of boiler at boiler room floor level.

"Instead of using doors, closure may be effected by water seal. This method may be described as a U-tube with one leg forming the hopper ashpit while the other is open to the atmosphere and possibly to the entrance of a clamshell bucket. Water in the bend of the U-tube forms a seal and serves to quench the ashes.

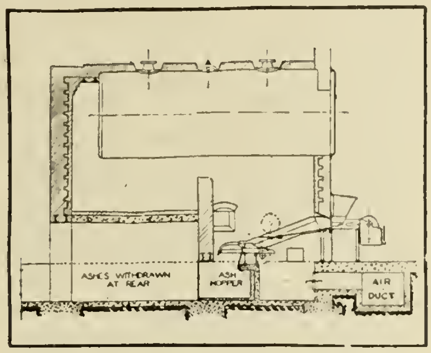

Fig. 1J—Ashes withdrawn at rear.

Water Sealed Ashpit

"An excellent example of this method is illustrated in Fig. 1F. The operation of this system is simple. More than sufficient water for the seal is provided by the waste cooling-water from the clinker grinders. The overflow is from one ashpit to the next, until it is finally discharged from the last ashpit.

"This system of ashpit requires considerable depth of basement; not less than 30 ft. from firing floor to basement floor."

Valve Opening Hints

The opening of steam valves and drain cocks should be done carefully, as many steam-pipe explosions have occurred when one boiler attendant has been replaced by another who was unaware of the order in which the valves and cocks were opened and closed.

The attendant should take it for granted that all low-lying steam pipes, especially long ones, all low-lying bends, junction valves, and all pipes between bulb valves are pockets in which water has settled while idle, and that large volumes of water will condense as soon as steam is turned into them. This water must be removed slowly, and very often much water in a pipe helps to create a vacuum, and as there is then no outflow a fairly full pipe may be thought to be empty.

A safe plan for coupling up a steam-pipe range is as follows: Open the drain cocks; these will either drain away the cold water or admit the air, which, if a water hammer should occur, will soften the blow. Close the cocks before opening the steam valve slightly. After a time close the steam valve and reopen the drain cocks. These operations may have to be repeated several times.

"THEORETICAL" MEN

To the mind of the average layman, an engineer is either a practical man or a theorist, with the college professor as the extreme example. By the same token the services of the young college graduate are frequently and perhaps universally depreciated by the time-honored conviction that his training has been confined to a sphere of knowledge entirely apart from anything encountered in the commercial solution of engineering problems. The fallacy in these contentions is apparent to the intelligent and tolerant citizen.

Theory is the summation of a long series of practical experiences, the possessor of the theory assimilating a digest of those experiences without the drudgery necessary to establish them. The difficulties which many employers are inclined to feel have been invited in hiring engineering graduates, are not infrequently results of an inability to understand or utilize latent possibilities. Despite opinions to the contrary, general opinion agrees that the young graduate is better equipped for inventiveness that his older confréres.

When the student casts aside the printed pages for those that the shop has to offer and when the man in the shop gleans the experience of his predecessors from the printed page, the line of demarcation becomes less real than imaginary. The engineer results.

VIBRATION VALUES

At first sight this title may seem to indicate a paradox. Vibration is generally regarded as an evil to be eliminated as far as possible. This form of motion very frequently makes itself directly evident in a manner unpleasant to the senses of hearing or touch, which probably in a large measure accounts for its general unpopularity.

Nevertheless, the subject is one that should receive consideration, not only with a view to facilitating the prevention of undesirable effects, but also in sight of the possibility of turning it to useful account.

It has been found that when the cooling water radiator of an internal combustion engine was mounted in such a manner that it was subject to what was considered excessive vibration, the cooling effect was improved 30 per cent. Again, metals under circumstances ordinarily influencing their decomposition have been found not to corrode so rapidly when under vibration.

There is no doubt that vibration has important effects on molecular and atomic conditions such as occur with heat engines, magnetic materials and chemical and other actions.

Boiler Tests a Vital Factor in Cutting Costs

Co-operation Between Management and Operator Works Wonders in Maintaining a High Average Efficiency Month After Month and That's What Determines Coal Pile Savings

WHEN a new boiler is purchased and installed the contract usually carries with it the purchaser's guarantee of efficiency which states that the company selling the boiler guarantees that the boiler so installed will have a guaranteed efficiency of boiler furnace and grates of not less than a stipulated per cent. when tested with coal of certain quality and under conditions specified. Every engineer and operator knows that before a boiler is tested it is carefully inspected, given a thorough cleaning and placed in prime condition.

The test is one of short duration ordinarily not exceeding 24 hours, frequently less and the boiler is usually operated at constant load and at its point of maximum efficiency. Selected coal is used for the test and skilled firemen are employed if it is possible to secure them.

Acceptance tests of this kind are very necessary and important since they serve to show what the boiler is capable of doing. They are also an indicator of how the boiler should be operated for best results. If tests are conducted at fairly regular and close intervals the results form a fair check on the plant operation.

However, a test of this kind does not represent actual operating conditions because of certain definite heat losses which are not accounted for in a short run. Boilers are not usually operated at constant load. In the average plant the load will be a widely varying one so that the boiler works at its point of highest efficiency only a small part of the time. When carrying a heavy overload or when running at much less than rating the efficiency usually is lowered materially.

Heating Surface Wanes

After a short period of operation the heating surfaces are less effective in conducting heat unless the soot is blown off at regular intervals. Soot blowing uses steam. Boilers are often banked at night causing a direct loss of heat not accounted for in a trial test.

Heat is lost when boilers are "blown off." Frequently blowing off is necessary when the feed water contains scale which settles in the bottom of the boiler. Bad feed water causes a heavy heat loss.

Analysis of flue gases may show a high percentage of CO_2 under actual test for 24 hours but average percentages are likely to be considerably less, indicating an excess of air and a consequent fuel loss. Very frequently little attention is given to the upkeep and the operation of a unit after it has been installed. The result is that a 24-hour test at normal rating often gives an efficiency of boiler furnace grates 10 to 15 per cent. greater than that shown by actual continuous operation over a long period of time.

Every day in your power plant peculiar conditions arise—"inexplainable. Isn't there a reason? Is there any satisfaction half as great as the discovery of the cause—the underlying law that governs an effect? When you refuse to seek a reason for a condition, the condition is your master. When you find the cause, you are its master.

You may never evolve an immortal idea but you can add something to the world's fund of information if you will untiringly seek the "why and wherefore."

Cut Heating Losses

Two factors mentioned above must be taken into account. One has to do with the necessary heat losses caused by the fact that actual average operating conditions are far from ideal. The losses caused thereby cannot be eliminated but may be kept low. Boilers must be blown off, but this loss can be minimized. Fires must be banked at night. However, records taken in some plants have shown that it is better economy to let the load run light on the whole battery of boilers rather than cut out one or more and carry a heavier load on the remainder.

The second factor is one which deals with the general condition of the plant. Heating surfaces can be kept clean if the operator is given the proper equipment and the incentive to use it. Scale can be kept out of the boiler. Air supply to the furnace can be closely controlled. Brickwork in settings can be kept in condition to prevent air leakage.

In short, the boiler can be kept in nearly as fit condition continuously as for a trial test, if attention is given to it. Coal should be selected with some care for it is almost always true that certain coals are better adapted to the operating conditions of the plant than other coals of equal cost and heat value.

A little additional equipment, a few extra appliances combined with a little knowledge, much interest and co-operation between management and operator will work wonders in maintaining a high average efficiency month after month. And high average efficiency is really the thing that counts because this is what determines the annual saving at the coal pile.

MAKING ICE IN A FURNACE

By Louis Craemer

Ice and melting clinker can be formed in the same furnace at the same time. It seems rather odd, if not impossible, but like Columbus and the egg, it's easy when you know how. The combination was anthracite with the usual amount of moisture, a traveling grate stoker, and forty degrees below zero weather.

I had been noticing that my fires were not in good condition, and I saw that unburned coal was going over the rear end of the stoker into the ash pit. The coal seemed to be in either large spots or, perhaps over the entire grate, and was underneath the usual burned out clinker.

I caught some of this coal on a shovel and found, to my amazement, that it was frozen solid. The explanation at once dawned on me. We investigated and found our forced draft fans were pumping outside air at forty degrees below zero through our fires, and literally freezing the coal next the grates while it burned freely at high temperature immediately over this frozen coal. Of course, we closed off the outside air and remedied the trouble, but for a while we actually made ice on our grates at the same time that we burned coal.

DESULPHURIZATION OF COKE

A study of the action of steam on coke, with regard to the reduction in sulphur content of the coke, is being made at the Pittsburgh, Pa., experiment station of the Bureau of Mines by A. R. Powell, physical organic chemist, and S. H. Thompson, research fellow of the Carnegie Institute of Technology.

PERSONAL

F. R. Allen, formerly with the Arthur S. Leitch Co., will shortly return to the same concern. Mr. Allen has been acting as manager of the Combustion Equipment Co. and it is possible the Arthur S. Leitch Co. may decide to represent some of the lines formerly handled by the Combustion Equipment Co.

Exhaust Steam Economy Vital to Fuel Saving

Effective Use of Every Possible B. T. U. Transmitted to Steam From the Fuel by the Boilers is Still of Decided Interest to Engineers in the Power Plants of Canada

THE economical and effective use of exhaust steam to-day, in the average industrial plant in Canada is becoming a factor of vital interest to the engineer. As a part of the problem involving fuel conservation, it requires far more attention than the layman would imagine.

In the past, a more or less general idea has been prevalent that once the latent energy of steam due to its high pressure, has been utilized, the residual steam is not of great account. Certain well operated plants under the supervision of high grade engineers might install condensers in conjunction with their main engines. This, however, was chiefly for the purpose of obtaining a partial vacuum, thereby to a great extent removing the resisting pressure of the atmosphere (i. e., 14.7 pounds per square inch at sea level), and increasing the power of the engine considerably. The engine would, thus, require less steam to produce the same power, than were it operating non-condensing.

To Effect Saving

In general, it was considered that the use of a condenser would save in the neighborhood of 20 per cent. of steam. On the other hand, the average plant, particularly of smaller type, in the first place could not afford a condenser installation, and in the second place could probably not realize its real value. Hence the engineer allowed his exhaust steam to escape, thereby losing in the neighborhood of 1150 potential B. t. u. in every pound of exhaust steam.

To-day the engineer is mainly concerned with the efficiency of operation in his boiler house and engine room. Fuel and steam economy is generally considered to be primarily his greatest problem. As efficiency improves so will general plant cleanliness and appearance, for the two go almost hand in hand and one cannot exist without the other.

Unit Cost of Steam

The average engineer has, in general, very little interest in fuel costs and steam accounting. Rather are bulk or volume figures of concern to him. The management, however, must consider these items if their operation is efficient, and through their accounting department they should have a monthly or even a weekly comparison of the unit cost of fuel per pound or b. h. p. of steam generated.

Here, we come to a mighty big consideration from the viewpoint of the management, the unit cost of steam produced. The question of effective use of every possible B. t. u. transmitted to steam from the fuel by the boilers is decidedly of interest to the management. When the maximum of developed heat energy is used where possible in plant process work instead of being allowed to dissipate into the atmosphere in the form of exhaust steam after the live steam has performed its primary function, then the fuel bills will be decreased, steam pressure on the main headers will be raised, the load on the boilers will be cut down, and sufficiently high pressure live steam will be available for usage where necessary to insure the greatest economy of operation.

> **Study, if you will, the whole history of mechanical development, and it will be at once apparent that the aim has always been, is, and always will be, to secure maximum attainment, in an economical manner, as quickly as possible; indeed but a moment's reflection will show that the principal aim of even the human body is economy in the expenditure of the bodily power and energy required to secure the attainment of efficient results.**

High Pressure Needs

There are, it is true, a great many stages in industrial plant process work where high pressure steam must be used because of the high degree of heating required, or for certain chemical reasons.

On the other hand, there are also a great many points where exhaust steam could be substituted for live steam to secure the temperature results desired. A part of the heat in the exhaust steam which would otherwise be wasted could thus be utilized.

With this in view we come to the kernel of the problem, from the viewpoint of the engineer, how to use the plant's steam most effectively, in order to reduce fuel bills by decreasing the consumption of live steam and hence the amount of fuel fired.

In practically every industrial plant, process work will be typical of the plant itself or of the product manufactured. Therefore no attempt will be made to mention considerable specific usage of such steam but rather, the possibilities that may cover all plants as a general rule will be considered.

An Economical Use

One of the most economical methods of utilizing exhaust steam is by a feed water heater in conjunction either with a condenser or hot well, or both. Thereby the heat contained in the exhaust steam, if the latter is collected from auxiliary machinery as well as the main units, is practically all saved by being transmitted to boiler feed water prior to its entry into the boiler. All plants, however, will not be equipped with condensing apparatus.

Hence, the problem may be limited to using the exhaust available for heating feed water in the reserve tank, should one be a part of the equipment.

If the exhaust steam contains an excessive amount of lubricating oils, etc., gathered from imperfectly lubricated engines or pumps, it can still be used for heating purposes via a heating coil in the feed water tank without the possibility of returning this oil to the boilers in the make-up feed.

Decide Steam Needs

There are many other points in practically every industrial plant where heating by steam is essential. Heretofore, the prevalent opinion has been that to adequately heat any such equipment, live steam must be used. This, however, will depend entirely upon the degree of heat required.

In such instances as grease-mixing kettles, sugar kettles and the many other types of process work so commonly found in industrial plants to-day, where a degree of heat approximating 200 deg. Fahrenheit as a maximum is demanded, exhaust steam up to 8 or 10 pound gauge pressure containing approximately 1160 B. t. u. per pound, will give ample heat for all requirements.

Use Good Judgment

For example, to heat a heavy, viscous grease mixture to 125 deg. Fahrenheit in a common kettle, steam jacketed, will require a greater volume of steam than a light oil heated by a double pipe coil.

Any number of such cases could be mentioned but they would be pertinent only to particular industries and hence of little service to this discussion. Suffice it to say that good judgment as to the rate of heating required will play an important part in determining whether exhaust steam could be used in place of live steam.

A little calculation of the number of B. t. u. required to raise the substance in question the requisite number of degrees, will frequently be most interesting provided the important points in the problem are known, such as, the specific heat of the substance, the inlet and outlet temperatures customary, the volume heated per hour, the pressure of the exhaust steam available, and the area of heating surface in use.

Efficient Boiler Selection

Human Element in Solving Problem of Actual Accomplishments

WE OFTEN hear of what it is possible to do with certain boilers or other devices in a power plant, how great savings can be obtained by doing one thing or another, all of which would be worth while were it not for the fact that too often these possibilities are ideal and not practical.

It is always desirable and even necessary to know ideal possibilities, but before we dangle them before a power-plant manager, let us determine if these novelties or improvements really show a net gain in the long run. The small plant particularly can not as a rule, use expensive apparatus requiring expensive operation.

The Human Element

The point is that high efficiency, capacity, etc., in a power plant is one of practical consideration in which the human element is perhaps the most important. It is all very well to talk about ideal conditions, but when making a choice, such as that of a boiler for a new installation, the practical end is the important one.

The first group of items to consider in selecting a boiler are space occupied, weight, capacity, first cost, adaptibility to particular conditions of operation and location. It is after the limitations set by these items have been fulfilled that the selection becomes difficult. The conditions then investigated are heating surface exposed to radiation; the correctness of the gas and water motions; workmanship; ease of cleaning, installing, examining and renewing tubes; and cleaning and repairing facilities in general.

Opinions Differ

The correctness of the water and gas motion is one item that causes much discussion and engineers differ in their opinions.

All, of course, agree that rapid circulation of the water is necessary to get good scrubbing action in order to remove the bubbles of steam from the wet surfaces. Rapid and free circulation can only be gotten, however, at the expense of some other item such as strength, ease of repair, expansion troubles, etc. To decide which boiler is the "happy medium" is a matter of personal judgment based on experience.

Space will not permit the consideration of each item mentioned above for the selection of boilers, but to illustrate the difficulty met with in forming a definite conclusion, take the case of the baffling which a boiler should have, a consideration which comes up when studying the gas motion.

The object of baffling is to direct the flow of hot gases. These baffles can be placed to cause the gases to flow across the tubes or along the tubes. Which shall it be? The points to consider when passing on the baffling are its influence on the heating surface, its cost of upkeep, ease of installation and repair, and its flexibility. The art of baffling is to minimize the inactive surface caused by dead gas pockets.

The conditions that carry out all these items can not be set down in exact mathematical terms and differences of opinion arise that can not definitely be settled. For example, it is desirable in a water-tube boiler to have the free area between individual tubes as small and the gas-pass as long as possible. The degree to which this can be done depends on the draft and it in turn is an item of cost. Therefore, the proper proportioning of these items is difficult and the personal element and experience always enter.

Efficiency Vital

So it is with any other item. We all desire high capacities, but there are practical limitations to capacities such as, for example, efficiency. It is difficult to determine the point in capacity beyond which efficiency drops off to such an extent that increase in capacity is obtained at a cost higher than that of additional heating surface. This point is approximately fixed, but the final decision is again a matter of judgment.

In the writer's opinion, the way to select a boiler for a new installation is to make a table of the following items, listing the limitations imposed by the conditions of the installation, and forming conclusions on actual practical results and not on any theoretical hypothesis:

Space occupied.
Weight.
Capacity.
First cost.
Adaptability.

After these items have been studied and the selection has narrowed down, the final selection is made by examining:

Surface exposed to radiation.
Correctness of water and gas motion.
Workmanship.
Ease of cleaning, installing, renewing, examining tubes.
General repairing facilities.

Each item is studied from the viewpoint of what has been accomplished in practice and what the boiler manufacturer guarantees. Theory can be studied, but it must be remembered that selection of boilers is not a research problem but a practical problem of actual accomplishments. The research and design phase of boilers should be discussed also and improved methods of steam generation studied. At any rate a healthy discussion of only one item at a time would be beneficial to all men in the field.

LIQUID SLIP REGULATOR

Peak loads may be materially reduced by the addition of a fly-wheel on the motor shaft and a means of utilizing the stored energy of this fly-wheel when peak loads occur.

This is accomplished with induction motors by increasing the slip of the motor at these periods through the introduction of resistance in the secondary circuits. This resistance may be in the circuit permanently or introduced by automatic slip regulators. The best known types of slip regulators are the magnetic contactor type, and the liquid type.

C.A.S.E. Notes

The 34th annual convention of the Canadian Association of Stationary Engineers will be held at the Central Technical School, Toronto on June 25, 26, 27 and 28. The 200 members of the C. A. S. E. in Toronto, of which R. McLaren, chief engineer of the Massey-Harris Co. is president, have energetic committees at work and a big successful convention is assured.

The Central Technical School has the best equipment on the continent for teaching practical operating engineering and this feature will attract many to the convention. There will also be lantern lectures and addresses by exhibitors in the auditorium, special contests, banquet, etc.

Invitations are being mailed direct to every engineer and manufacturer in Toronto and nearby cities and towns. Other invitations are being prepared for exhibitors to send to their customers.

This is a good opportunity to meet engineers and other industrial representatives personally.

As spaces are allocated as orders are received, it is an advantage to reserve space now. A booth is $25 or table space $10.

Special provision has been made for heavy exhibits of stokers, large grates, etc., a room with a concrete floor being available for this class of equipment.

The regular meeting of Toronto No. 1 C. A. S. E. was held April 3rd in Cumberland Hall. The subject for discussion, in connection with the Educational Program, was Boiler Efficiencies and Evaporation Tests.

Real Economy

THE lesson of economy is hard to learn. It is beset by powerful temptations and steadfast determination is required to master them.

Money spent to-day for more efficient apparatus takes care of the "rainy day" tomorrow.

In applying this type of thrift to power plant problems—by forcing the expenditure of money for the things necessary for the intelligent conduct of your everyday duties—you are not only doing something tangible to lower the operating cost of your employer's plant but you are giving impetus to the motion of the present tide of business.

Mr. Manufacturer.

SERVICE—that's the present-day price of success!

It's what the power plant engineer demands, for he knows that modern machinery is constantly being improved with regard to facility of operation and the necessity for doing things "right" is apparent to him on every hand.

The high cost of power interruption forces him to realize that care taken before trouble arises is a gilt edge investment.

A prime mover that runs "perfectly" is always due to conscientious work in the factory and painstaking installation in the power house.

Get busy—think of some new service for the man, who, surrounded with automatic control systems and safety devices is to-day obtaining results surpassing those obtained by ten of his fellows in the not very distant past.

Your opportunity is here—but the other fellow is going to grab it if you don't hurry.

Practical Knowledge

MUCH knowledge which the world has acquired with inordinate travail and entravagant expenditure of time and money is summed up by science to-day in a few definite laws and principles.

In no field is greater use made of these laws than in that of engineering, yet there remain many complex problems in which the engineer has to make good with but little, if any, aid from science.

An example of the long ago often cited is the high degree of perfection to which the reciprocating engine was brought, in spite of the lengthy "time lag" in the science of thermodynamics. Steam engines were running successfully long before Joule had determined his equivalent and subsequent to this many decades elapsed before the development of thermodynamics had become of any practical service to the engineer.

Is it not the case that to-day in engineering schools many students too often learn to calculate, and having acquired facility, become indisposed to think? It must at least be admitted that it is much easier to find a student who can determinate accurately the reaction exercised by a steam jet than to find one who can picture the mechanism by which this reaction is impressed on the nozzle box.

The older school of engineers, less adept perhaps in mathematical methods, were forced to think mechanically in forming mental pictures of the distribution of the forces in which they were interested.

To-day a student with his slide rule can solve in a few minutes problems on which his predecessors spent hours; but should his knowledge be superficial, he is liable to go astray when confronted with every-day power house problems for which, as yet, formulae supply no remedy.

Building Confidence.

THE action of the American Society of Mechanical Engineers, in adopting a code of ethics as a rampart for the protection of the reputation of each individual in its membership of 20,000, is striking proof of the determination of the modern engineer in every field to build for himself a bulwark which will protect and conserve his career. Ultimately it is expected the principles of this code, which rest on the very foundation upon which the structure of society is built—confidence—will apply to the entire engineering profession.

In the power plant field in Canada it has long been recognized that it is best to deal fairly and honestly. Manufacturers and engineers in every walk of life are well aware that confidence is the basis on which their ultimate success must rest—that "a man who is poor in trust is the poorest of God's creatures."

Confidence manifests itself every day in our actions toward one another. A power plant owner must believe in the knowledge of his engineer, for knowledge alone can beget that confidence in the man in responsible charge of a plant essential in making his advice and equipment recommendations worth while.

Heating and Ventilating

THE objects sought by heating and ventilation—the maintenance of the air and temperature in a building in the best possible condition for the health of the people using it—are so interdependent that it is always unwise to consider them apart.

In an interesting experiment recently concluded in England an airtight glass case was constructed of sufficient size to allow two or three men to stand upright inside it and an electric fan was installed, operated by a switch outside.

The men were shut inside the case and allowed to breathe the contained air until they began to show signs of collapse, indicating that the proportion of carbon dioxide had risen very considerably and the proportion of contained oxygen was seriously diminished. The electric fan was then set in motion, with the result that the men immediately revived, regaining their normal feelings entirely in a very short time after their liberation.

This experiment would tend to show that chemical purity is not of the same relative importance as that of the movement of air.

Questions and Answers

Queries are invited on the every-day problems of engineers in all industries. Correspondents should sign communications with their full names and post office addresses, which will be withheld on request.

Overhauling Boilers

What is the proper method of procedure when a boiler is to be cut out of service in order to give it a thorough overhauling?—A. N. W.

Burn down fires until all available heat has been extracted, at this point there will be a drop in pressure with damper wide open, meantime the water level has been regulated so that it shows near bottom of glass. Shut all steam valves on boiler, admit some feed water to prevent a rise of pressure to blow off point and then close all dampers. Allow boiler to stand 24 hours before emptying so that it will cool off gradually, keeping the scale and mud soft and easy to remove.

Centrifugal Pumps

On what does the action of centrifugal pumps depend?—O. A.

Centrifugal pumps depend for their action on the pressure produced by the centrifugal force of a quantity of water rotated rapidly by the vanes of an impeller and then thrown out at the periphery. The partial vacuum formed in the centre allows the atmospheric pressure to force water through the suction opening to replace that continually thrown out by the impeller.

Boiler Corrosion

Is zinc of any value in preventing boiler corrosion?—A. H.

Boiler plate corrosion is sometimes due to galvanic action. By placing zinc plates inside a boiler a galvanic action is sent up which attacks the zinc first, destroying it, and leaving the boiler plates unharmed. The zinc is renewed as often as required.

Safety Valve Hammer

How can I eliminate the hammering of a spring-loaded safety valve on a boiler?—O. M., Toronto.

The hammering is probably due to too long or too short a connection for the valve as, under such conditions, when the steam pressure in the boiler rises to the pressure at which the valve blows off, there would be rapid alternations of higher and lower pressure under the valve to synchronize with vibrations of the weighing spring. With the majority of spring-loaded safety valves, however, the hammering of the valve can be eliminated by increasing the amount of "blowdown" of the valve.

Clinkering Coal

I am using coal in a hand-fired boiler that clinkers badly. How can I fire my boiler to reduce the trouble?—B. N., Toronto.

Carry a thin fire, promptly covering the brightest spots of the fuel bed with fresh coal to prevent holes from burning through to cause the coal to drop to the ashpit. Stir the fire as little as possible. Keep the bed level by stoking. Levelling the fuel bed with firing tools is likely to cause clinkering by gathering together the ash or shifting the ash to a hotter part of the fuel bed.

Maintain the ashpit as cool as possible, keeping the doors open and regulating the draft with the uptake or stack damper. Promptly quench any ashes or coal that may fall through the grates and should the ashpit be watertight, keep water standing in it. Should that be impracticable, blow steam under the grate. A pump exhaust or any other supply of waste steam turned into the ashpit will prove beneficial.

Wire Wound Coils

Is there any advantage in increasing the number of turns in the rotor of a wound-rotor induction motor?—A. W., Montreal.

Increasing the number of turns in a wound-rotor induction motor increases the voltage between collector rings and decreases the current, making possible collector rings and brushes of a smaller capacity. This simplifies and cheapens the control as the providing of cast-iron grids or other forms of resistance increases when the current exceeds a certain value. The minimum limit to this is reached when the cross-section of such grids is as small as it can be made for mechanical strength and there is no advantage to be gained in reducing the current below that point.

Code of Ethics

I understand the American Society of Mechanical Engineers recently adopted a code of ethics and if I have been correctly informed I would like you to publish the salient points in it?—Engineer.

You have been correctly informed. The code commands personal honor, fairness to contractors and workers, and interest in the public welfare. The text, adopted by a membership of approximately 20,000, is as follows:

"Engineering work has become an increasingly important factor in the progress of civilization and in the welfare of the community. The engineering profession is held responsible for the planning, construction and operation of such work and is entitled to authority which will enable it to discharge this responsibility and to render effective service to humanity.

"That the dignity of their chosen profession may be maintained, it is the duty of all engineers to conduct themselves according to the principles of the following Code of Ethics:

"1. The engineer will carry on his professional work in a spirit of fairness to employees and contractors, fidelity to clients and employers, loyalty to his country and devotion to high ideals of courtesy and personal honor.

"2. He will refrain from associating himself with or allowing the use of his name by enterprises of questionable character.

"3. He will advertise only in a dignified manner, being careful to avoid misleading statements.

"4. He will regard as confidential any information obtained by him as to the business affairs and technical methods or processes of a client or employer.

"5. He will inform a client or employer of any business connections, interest or affiliations which might influence his judgment or impair the disinterested quality of his services.

"6. He will refrain from using any improper or questionable methods of soliciting professional work and will decline to pay or to accept commission for securing such work.

"7. He will accept compensation, financial or otherwise, for a particular service, from one source only, except with the full knowledge and consent of all interested parties.

"8. He will not use unfair means to win professional advancement or to injure the chances of another engineer to secure and hold employment.

"9. He will co-operate in upbuilding the engineering profession by exchanging general information and experience with his fellow engineers and students of engineering and also by contributing to the work of engineering societies, schools of applied science and the technical press.

"10. He will interest himself in the public welfare in behalf of which he will be ready to apply his special knowledge, skill and training for the use and benefit of mankind."

Water of Condensation

What provision is made in vertical engines for getting rid of water accumulations on the top of pistons?—A. R. A., Brantford.

A somewhat similar query was answered several months ago in Power House but for the benefit of many new subscribers since the dawn of 1923 we would repeat that when warming up, preparatory to starting, and during the first few minutes of running, water of condensation is taken care of by the drain cocks, a certain amount also being carried away with the exhaust through the slide valve opening.

When the engine is running up to normal speed and load, there is usually provision for a sudden slug of water in the shape of a spring-loaded relief valve of ample size to relieve the cylinder.

In some types of engines the valve itself is held up to the face by a spring, which is heavy enough to hold it under ordinary conditions, but will allow it to lift from the face under a sudden shock such as that caused by the presence of water in the cylinder.

Water in the cylinders materially impairs economy in the use of steam but if it is carried over with the steam in large quantities it can be guarded against by the use of suitable separators. What cannot be avoided in ordinary engines with saturated steam, is the condensation of a certain amount of the steam on its admission to the cylinder, due to the cylinder walls having been cooled off during the exhaust period of the previous stroke.

This condensation represents a distinct loss. If there is water constantly present in the cylinder the loss is, of course, considerable, but generally the condensation which has occurred during admission is re-evaporated during expansion.

If the engine is a simple one, that is, single cylinder non-condensing, this reevaporation is of no value as the heat abstracted from the cylinder walls to perform the evaporation is merely carried away in the exhaust.

If the engine is a compound one, we get the benefit of this heat in the next cylinder.

Differential Pumps

To settle an argument will you tell me the purposes of the two plungers of a differential pump?—Robert Steel, Montreal.

One plunger of a differential pump acts between the suction and delivery valves, operating them, while the other is on the discharge side or on top of the discharge valves. The plunger between the valves has twice the cross-section area of the outer one. On the suction stroke the large plunger lifts a volume of water equal to twice the volume of the smaller plunger and on its return stroke it drives this volume through the valve, however, as the smaller plunger is now receding, one-half the volume of the water fills up the space left by it, the remainder being discharged out of the pump.

Radiator Paints

Could you give me any idea of the relative efficiency of bronze and enamel pipe and radiator paint?—H. W.

Painting a bare pipe with gold or aluminum bronze, recent tests indicate, decreases the efficiency of the radiating surface about 20 per cent. but if a coat of white enamel is applied on top of the bronze approximately 95 per cent. of the original efficiency will be restored.

All radiating surfaces dissipate heat as the result of conduction, convection and radiation. The dissipation due to conduction and convection varies in proportion to temperature difference, while heat lost by radiation varies as the fourth power of the absolute temperature. This means that if the absolute temperature is doubled, the heat radiated is increased 16 to 1.

At low temperatures the portion of total heat dissipated by radiation is small, so that the difference in the efficiencies of the two paints is less than at higher temperatures, because while the radiant energy given off by the enamel increases very rapidly, the mirror-like surfaces of the bronze hold this component of the total heat down on higher temperatures and consequently cause a greater difference in the heat dissipation of the two classes of paint to result.

Gas and Coal

Can you tell me how many thousand cubic feet of natural gas with 1,000 B. t. u. per cubic foot equal 1 ton of coal containing 11,000 B. t. u. per lb.?—W.S.

One short ton of 2,000 lbs. of coal containing 11,000 B. t. u. per pound is equivalent to 22,000 cu. ft. of natural gas containing 1,000 B. t. u. per cu. ft. One long ton of 2,240 lbs. of the same coal is equivalent to 24,640 cu. ft. of natural gas of the same thermal value.

$$\frac{11{,}000 \times 2{,}000}{1{,}000} = 22{,}000 \text{ short ton basis}$$

$$\frac{11{,}000 \times 2{,}240}{1{,}000} = 24{,}640 \text{ long ton basis}$$

One short ton of this coal is equivalent to 3.52 barrels of fuel oil, specific gravity .9589, containing 18,640 B. t. u. per lb., or 6,255,111 B. t. u. per barrel. One long ton is equivalent to 3.94 barrels of this same oil.

$$\frac{11{,}000 \times 2{,}000}{6{,}255{,}111} = 3.52 \text{ short ton basis}$$

$$\frac{11{,}000 \times 2{,}240}{6{,}255{,}111} = 3.94 \text{ long ton basis.}$$

Practical Gasket Hints

By Henry Bohmer, Jr.

The greatest difficulty I have encountered during my ten years of experience with gaskets has been to convince engineers that it is not necessary to tighten a thick flexible metallic gasket with the same extreme pressure as must be applied to thin non-flexible gaskets.

The idea seems to prevail that a gasket, in order to prevent leakage, must have as little thickness as possible and must be squeezed so thin that the distance between the faces of the flanges is a very close approach to absolute zero.

Very often when applying gaskets we see the engineer or pipe fitter slip a pipe over the wrench, thereby increasing the wrench's leverage and making it possible to still further increase the pressure against the gasket. As a result the gasket is squashed. If it is made of corrugated metallic material it is flattened out so much that the corrugations can do no good whatever.

Adopt Safety Measure

It is poor practice to slip a pipe over any wrench on any gasket because wrenches are generally made of a proper and safe length to fit the nuts for which they were intended, and nut sizes are usually standardized to fit certain bolt diameters. This is a logical safety measure that has been almost universally adopted so that the bolt will not be subjected to too great tension. An extra long handled wrench, unless used with extreme care, is liable to either break the bolt or strip the threads.

One serious objection to the very thin gasket is that no matter how it is constructed it can have but little expanding or contracting capacity, consequently all expansion and contraction must be taken care of in some other manner—by means of pipe bends or expansion joints. A thicker gasket, having elastic properties, will naturally take care of considerable expansion and contraction. In many cases I have known thick flexible gaskets to take care of all the expansion and contraction in the line—under ordinary temperature conditions of non-superheat practice.

To Avoid Leakage

Where temperatures are high, or where temperatures fluctuate considerably, copper, brass and other metallic gaskets having a co-efficient of expansion different than that of the joint, should not be used. On account of the difference in the co-efficient the gasket and the joint tend to expand and contract independently of each other. The tightly bolted joint being much stronger than the thin gasket will compel the gasket to expand and contract along with it. Breakage and leakage of a serious nature are, therefore, often the result.

A gasket made up of steel, which has the same co-efficient of expansion as the joint, overcomes this latter trouble entirely, but if it is thin and non-flexible it does not overcome or assist in overcrowding the longitudinal expansion troubles.

Use Proper Wrench

Hence when applying thick flexible metallic gaskets, be certain that a

(Continued on page 40)

The Operator's Point of View

The Key to Success

I am glad to see that Power House takes an interest in its subscribers, for that is one of the things that assure it of lasting success.

Now as to the feeling of the few engineers who think they are paying for the advertising pages let me tell you that with all the different kinds of machinery that are being made nowadays if a man can't afford innumerable costly sets of books he can get a lot of valuable information by studying the advertisements in Power House.

There is another thing I like about Power House and that is that it tries to help any man who is in a hole, out of it and that is something every publication does not do.

I would sooner pay $2 a year more for a small book full of good information than $10 a year for a large book full of worthless information. I save every copy of Power House I receive, putting each copy away after reading into my bookcase for future reference.

I know that Power House is going to help me secure my second class papers within a few months and any time I can suggest any new ideas I will gladly send them along, although I am out of work at present.

L. G .ACKROYD, 199 Van Horne St.,
Toronto, Ont.

A Hint to Employers

I am sure many of your readers who have answered advertisements in technical publications or newspapers would be grateful if employers were to announce, in the medium in which their advertisement appeared, when the position had been filled, as there is always a certain amount of satisfaction in knowing that a matter is definitely closed and if you will publish this letter in Power House I will appeal to employers to make a practice of doing so.

Surely they often overlook the fact that the obligation is not entirely on the part of the applicant but a mutual affair.

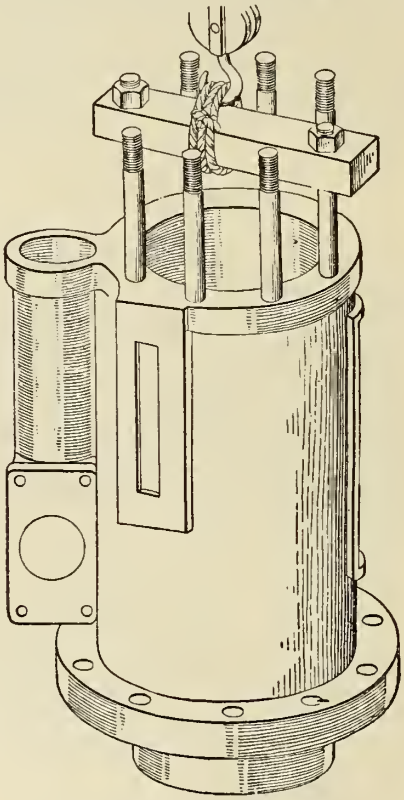
Another point I would like to make is that, in my opinion, employers do not generally give sufficient data regarding the vacancy in their advertisements, such as the size and approximate location of the plant, the nature of the industry for which the power is generated, etc., as if fuller information were given it would often, I feel sure, prevent engineers seeking posts they are unlikely to obtain, either because their qualifications are greater than those required and the salary asked greater than the position carries, or the reverse.

You will I hope try to find space for this letter, as it does seem to me that anything that can be done to make things easier for any member of our profession, who is at present out of work, should be done.

There is no doubt in my mind that it is simply failure to realize the other fellow's point of view that once in a while makes employers rather remiss in this respect.—M. E.

Handling Engine Cylinders

A few months ago I was called in to help to overhaul two oil engines. In removing the cylinders, which were to be rebored, the engineer started to wrap a chain about the cylinder head studs with the intention of looping it over the crane hook. I prevented him from doing this as I feared it would bend the bolts.



Lifting Cylinders With Care

We then obtained a 6 by 6 timber and bored two holes in it large enough and far enough apart to take the two opposite studs. We then passed a sling around the timber and on to the crane hook as shown in the illustration. This plan removes all danger of bent studs. The pull on the studs is vertical and the cylinder will lift off the holding down studs without any trouble.—J. S.

Iron Pipe Sizes

The following information will be new to some of the younger generation of engineers and of interest to others.

Practically all engineers handle standard iron pipe from ⅛ inch up. Most of them have to do with sizes such as 8 inch, 10 inch or larger. There are men who talk about ⅛, ¼, ⅜, ½ and ¾ inch iron pipe and other sizes who would be surprised when told that the internal diameter of these pipes are altogether different from the named sizes, and if they do know it they have not taken the trouble to find out the reason the pipes are not made the sizes their names indicate.

Take as an illustration the five small sizes named, their internal diameter will closely approximate ¼, ⅜, ½, ⅝ and 13/16 inch respectively. Sizes above 11 and 12 inches are usually named according to their external diameter.

The reason given for this apparent ambiguity is quite feasible when known. There is standard, heavy, extra heavy and double extra heavy iron pipe. Each grade has a different thickness, the heavier the thicker, of course. If the extra thickness was added to the outside diameter there would be great difficulty in threading the pipes and no possibility of threading them at all with solid, or one piece bushings, and one piece dies. If the standard ⅛, ¼, or ⅜ inch pipe was made with an internal size the same as named there would be very little opening through them when the internal area was reduced in forming any of the heavy grades.

JAMES E. NOBLE,
173 Macdonell Ave.,
Toronto, Ont.

Over 99 Per Cent.

The write-up of the Regina Parliament Buildings Power Plant in a recent issue of Power House calls for a few comments from engineers interested in efficiency and furnace design.

I am afraid the "special correspondent" proved the efficiency of Mr. Blackburn, the chief engineer, but neglected completely to verify the wonderful boiler efficiency corresponding to the claimed evaporation of 9.99 pounds water per pound of Drumheller coal. I have no hesitation in saying this claim is ridiculous. If the clamed evaporation were correct, it would mean that the boilers were giving an efficiency of about 99½ per cent. Readers can verify this for themselves from the heat value of the coal in question. The best grade of Drumheller coal as tested by the Research Dept. of the University of Alberta, gives 10,185 B. T. U. per pound;

and the average of nine mines in that district as 9960 B. T. U. Hence, a boiler that utilized all the heat units could not possibly evaporate more than about 10.5 pounds water per pound best grade coal. It is to be noted that the special correspondent states that the water is "frankly bad," and yet in his evaporation calculation he makes no allowance for loss due to blowing down.

It is quite likely that the boilers in question are giving average efficiency which is nearer 6 pounds water per pound coal than 9.99 pounds as claimed. If they are evaporating more than this, then the special correspondent would be doing western engineers a favor by giving them some details of the furnaces and the operation of same.

Of course, in a small plant like the one described, with only two boilers and two first-class engineers in charge, not to mention the assistant engineers, one would naturally expect rather better than average efficiency.

J. A. CARRUTHERS, M. M., Lethbridge, Alta.

IGNITION OF COAL

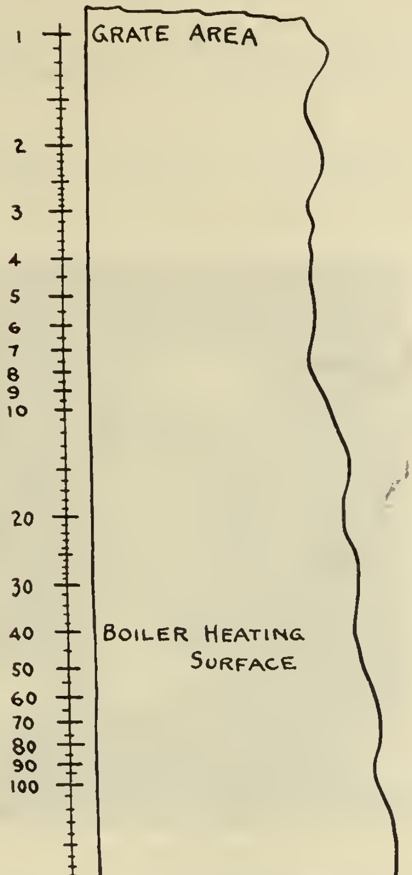
There is no definite temperature at which coal bursts into flame. The phenomenon of flame from coal is due to the combustion of volatile matter driven off from the coal, the character of such matter varying under different conditions; hence, the temperature at which the coal flames varies widely and is dependent upon surrounding conditions, and therefore the flaming temperature of a coal does not serve as an indication of the ignition point. Strictly speaking, it is the true ignition point, but since it varies so widely its valuation is meaningless. Moreover, any definition of ignition temperature based on the spontaneous emission of heat from coal is equally unsatisfactory, because experiments have proved that coal is giving off heat of combustion or some phenomenon akin to combustion at all temperatures. To be sure, the combustion at low temperatures is slow, but it is nevertheless evident. As the coal is raised in temperature by an outside source of heat it produces more and more heat from its own combustion, but there is no point in this process where the change in rate of heating is sufficiently abrupt to be regarded as indicating a definite ignition temperature.

Proportioning Charts

Here is a proportioning chart that will be found practical in more ways than one.

For example, a well known ratio in hot water boilers is 1 to 40 to 200, the areas being respectively the grate area, the boiler heating surface and the radiating surface.

For any boiler, then, all you have to do is lay a slip of paper alongside the scale as I have indicated and make marks opposite the 1, the 40, and the 200. For any radiating surface, now, all you have to do is—move the slip of paper downward to whatever radiating surface is wanted and the two upper marks will immediately tell the grate area and the boiler heating surface without the need of figures or even mental calculations. Just try it and see how easy it is.



Proportioning Heating Chart

For instance, 1000 ft. radiating surface, bring the lower mark down opposite that figure and the upper lines will tell that the grate area must be at least 5 sq. ft. and the boiler heating surface must be 200 sq. ft.

No matter what proportions you want to work out, and no matter how many different figures there may be, they can be all proportioned at once in the same way.

A little experimenting will quickly show you in how many different ways a scale of this kind may be used. It can be used for recipes, multiplying, dividing and proportioning.

W. H. SCHAPHORST, M. E.

Personals

W. C. Hall is in charge of the new office the Canadian Comstock Co. has opened at Room 28, 18 Toronto St., Toronto.

Ben F. Lamson, for the past four years assistant city engineer, has been appointed city engineer of St. Catharines, Ont., at a salary of $3,000 a year.

John T. Farmer, chief engineer of the Combustion Engineering Corporation, with offices at 314 Corictine Bldg., Montreal, was at the head office of his company in Toronto, Thursday, March 29th. He reported a very optimistic business trend in the Montreal district. Mr. Farmer was recently elected chairman of the Montreal section of the Canadian Association of Mechanical Engineers.

A. J. T. Taylor, president and general manager of the Combustion Engineering Corporation, is now in Vancouver, B. C., arranging for the removal of his family and household to Toronto. He is expected to return to the city about April 10th. Mr. Taylor formerly was president and general manager of the Taylor Engineering Co. of Vancouver. The latter company is now acting as Western representative of the Combustion Engineering Co.

T. M. Jones, formerly sales engineer of Clayton, Neil, Jones, engineers and manufacturers of rotary pumps, with works at Sault Ste. Marie, left April 6th for Manchester, England, where he will be associated with the firm of Mather & Platt. The Toronto office of the Sault Ste. Marie firm is to be closed so that all business can be transacted by Mr. Neil from the office at the works.

W. L. McFaul, former deputy city engineer, has been appointed city engineer and manager of the waterworks department of Hamilton, Ont., for a period of six months. Mr. McFaul will assume his new duties April 14. He graduated from Toronto University with the degree of Bachelor of Applied Science in 1913. From then until May, 1914, he was employed as an assistant in the city engineer's department of Arthur, Ont., on waterworks, street railway and roadway construction. From

May, 1914, until September, 1916, he was Assistant City Engineer, Sault Ste. Marie, Ont., having charge of all work on roadways, sewers, sidewalks and bridges.

In September, 1916, he was appointed City Engineer of Sault Ste. Marie, and held the position until June, 1921, except for the period from November, 1917, until February, 1919, during which time he was in the Canadian army and overseas.

F. H. Breor, formerly associated with the Arthur S. Leitch Co., has joined the sales force of the Combustion Engineering Corporation.

A. W. Roberts, manager of the Allen General Supply Co., 105 Yonge St., Toronto, who has been ill for two weeks suffering from sciatica, has returned to his office.

The annual meeting of the Corporation of Professional Engineers of Quebec was held at the headquarters of the Engineering Institute of Canada in Montreal. A large number of members attended from all parts of the province and officers were elected for the ensuing year. The meeting was presided over by A. R. Decary, M.E.I.C., superintendent engineer for the province of Quebec and newly-elected president of the corporation.

The report for the year showed that the membership has now reached 921, an increase of 416 since 1921. The following were elected to replace the retiring councillors: For the district of Montreal, C. N. Montserrat, Olivier Lefebvre and J. M. Robertson; for the district of Quebec, J. E. Gibault.

The election of officers then took place with the following result: President, A. R. Decary, M.E.I.C.; vice-president, K. B. Thornton, E.E., M.E.I.C.; honorary secretary-treasurer, Frederick B. Brown, M.Sc., M.E.I.C. The other members of council are—J. M. Robertson, M.E., M.E. I.C.; Lt.-Col. C. N. Montserrat, M.E.I.C.; Olivier Lefebvre, B.Sc., M.E.I.C.; A. B. Normandin, B.Sc., A.M.E.I.C.; J. E. Gibault, B.Sc., A.E.I.C.; registrar, Adhemar Mailhiot, B.Sc., Mem. C.I.M.M.

Building Hints

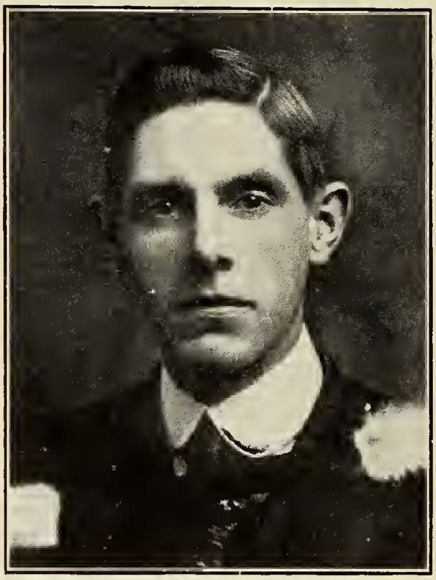
Barnes Manufacturing Co., Detroit, manufacturers of scales, will open a factory in Windsor, Ont. A suitable building has been leased at 325 Assumption Street, Windsor.

Board of Education, Peterboro, Ont., have approved the erection of a combined Collegiate and Vocational School to cost approximately $500,000. The grant from the government towards this project is $140,000.

Coast Range Steel Co. are now occupying permanent offices on the 14th floor of the Standard Bank Building Vancouver. The company is a British concern, and preparations are now being made to install blast furnaces in the plant at Vancouver. H. J. Landahl, one of the officials of the company, has just returned from England where plans are being approved. John Steta is the secretary at the Vancouver office.

One thousand men are now employed on the new power project on the St. Maurice River in Quebec Province. The undertaking is being engineered by the St. Maurice Power Co., and when completed will mean an additional 120,000 h.p. for the Shawinigan Power Co.

There is a project on foot at St. Catharines to build an artificial ice arena to cost approximately $135,000. A site for the building has already been secured. It is expected that the arena will be ready for the hockey season this year.



W. G. WOONTON, B.A.Sc.

W. G. Woonton, chief engineer of the McCormick Manufacturing Co., London, was formerly lecturer in the Department of Electrical Engineering, University of Toronto. He also for a time was chief engineer of the London Street Railway, assistant mechanical engineer of The British Acetones, Toronto, and lecturer for the Khaki University of Canada in various camps in England, Ireland and Scotland.

Hospital for Incurables, Montreal, which was recently destroyed by fire, will be rebuilt at a cost of $1,000,000. It is proposed to combine with it a hospital for tubercular patients. Tentative plans have received the sanction of Archbishop Gauthier.

The members of the Gas Committee of the St. Thomas, Ont., city council in session April 3 recommended that a new purifying set, estimated to cost $20,000, be installed as soon as possible at the Municipal Gas Works, and that application be made to the Ontario Municipal and Railway Board for permission to issue debentures to cover the cost. Superintendent Robert Christie reported that a second bad break had appeared in one of the steel tanks at present in use, and both life and property were endangered by the condition.

Authority for the construction of an electric or steam railway from Emerson, on the international boundary, to Fort Churchill, on the Hudson Bay, is asked for by the Manitoba Waterpower Electrical Company in a bill introduced in the Manitoba Legislature April 3. The railway would run through Winnipeg to the north via the eastern shore of Lake Winnipeg, the provisions of the bill show. The company is in no way associated with the Manitoba Power Company.

The greatest announcement in many years in connection with industry in the district of Timiskaming is the report from Quebec City, which declares a lease is to be granted on April 25 to interests who will develop Des Quinze Rapids, at the north end of Lake Timiskaming. Telegrams sent to the Quebec capital have not yet brought definite advices as to who the interests are who are securing the right to develop not far under 100,000 hydro-electric horsepower.

The two known facts are that the lease is to receive sanction of the Quebec government on April 25, and that the condition applying to Ontario is that the Quebec government will impose an export tax of 50 cents per horsepower.

Feed Water Heaters in Their Relation to Steam Plant Efficiency.—H. S. B. W. Cochrane Corp., Philadelphia, Pa., Canadian Representative, Canadian Allis Chalmers Co., 212 King St. W., Toronto, Ont. Publication No. 1112 describes the influence of feed water heating upon steam plant efficiency and touches briefly on the various types of Cochrane apparatus for measuring, heating and treating boiler feed water.

In the Power Plant.—Hicarb is a refractory having heat resisting properties withstanding temperatures far beyond those found in the extremes of actual service. It is also proof against the action of acids, rust and corrosion.

When painted over the surface of fire brick linings it retards fusing and burning out thus prolonging their life. It is also used on terra cotta, concrete and metal surfaces for the same purpose.

Cracking, chipping or breaking off of pieces of fire brick is also prevented by its use. Clinkers do not form readily, and the few that do are easily brushed off with the slicer bar with no possible danger of taking part of the lining.

Its makers, Adams & Jewell, Rome, N. Y., claim that Hicarb increases the life of all furnace linings 50 per cent. to 100 per cent.

BABCOCK & WILCOX, LIMITED

Toronto Office:
Bank of Hamilton Building

ST. HENRY—MONTREAL

A manufacturing plant in which low pressure steam for process purposes is supplied from a turbine of special design is described in a profusely illustrated leaflet issued by the De Laval Steam Turbine Co., of Trenton, N. J.

This turbine operates automatically either as a straight condensing turbine, as a back pressure turbine, as a bleeder turbine, or as a mixed flow turbine or as a low pressure turbine, in such a manner as to maintain a balance between power requirements, low pressure steam requirements, hot water requirements, and the amount of power available from water power.

This is accomplished by a third pressure in addition to the high pressure and low pressure valves ordinarily controlled by the steam governor in a mixed flow turbine. The utilization of exhaust steam for heating and process purposes, or the production of power as a by-product from steam used at low pressure, offers surprising economics, and this leaflet will, therefore, repay careful study in these times of high fuel costs.

Announcements

An order of record size has just been received by the Canadian Allis-Chalmers Ltd., Toronto, for the supply of hydraulic equipment to the Quebec Development Corporation. This corporation has already commenced construction work on its power plant on the Saguenay River, close to Lake St. John, which calls for an ultimate installation of twelve turbines of 37,500 h.p. capacity each.

The order received by the Canadian Allis-Chalmers is for the first eight of these units. The turbines will be of the vertical type, 112½ r.p.m., 37,500 h.p. at 9/10 gate opening.

Construction has been started by Dwight P. Robinson & Co., Inc., on an extension to the "South Power Station" of the Aliquippa Works of the Jones & Laughlin Steel Corporation, near Woodlawn, Pa.

The improvement includes preparation of site, foundations and condenser well, and the erection of an extension to the building to house a 10,000 k. w. steam generator unit with condenser and all other appurtenances. The installation of a new turbine driven pump in the pump house, with connections to steam and water mains, is also included.

Dwight P. Robinson & Company have also under way in the Pittsburgh District an extensive addition to the Colfax Station of the Duquesne Light Company.

The Charter Gas Engine Company of Sterling, Ill., announces the purchase of the entire "Meitz" Oil Engine (also known as "Meitz and Weiss") business, heretofore carried on at 128-138 Mott Street, and 430 East 19th Street, New York City, by the August Meitz Corporation and the Reliance Oil Engine Corporation.

The first "Meitz" Oil Engine was built in 1895 by Meitz and Weiss.

The Charter Gas Engine Company are now moving from New York City to their plant at Sterling, Ill., all of the physical assets comprising the "Meitz" Engine and in the meantime are filling repair orders from New York City, so that there will be no interruption in repair service to "Meitz" engine users.

A number of the personnel of the August Meitz Corporation organization have been engaged for work by the Charter Gas Company, insuring a thorough working knowledge of the manufacture of "Meitz" engines.

Book Reviews

Longmans-Green & Co., "Elementary Internal Combustion Engines," 207 pages, price $1.75.

Gas, oil, petrol and other combustion motors are outlined along elementary lines in this work. Features of the two-stroke and four-stroke cycle types are compared and collated. The general design and points of construction of governors are touched upon, while the subject of ignition is explained and illustrated in some detail. Indicating of gas engines is developed graphically including an interpretation of the diagrams frequently obtained.

In connection with gas engines is a chapter of gas producers, describing the performance of several well-known types. The theory of the operation of the gas producer is illustrated in detail by numerical examples.

The chapter on oil engines, which is a new feature in this edition, gives much in the way of illuminating information on Diesel and semi-Diesel engines.

"Elementary Internal Combustion Engines" is a clear exposition of the subject, logically arranged.

Longmans, Green & Co., "Efficient Boiler Management," Charles F. Wade, 266 pages, illustrated, price $4.50.

Much has been written concerning the very general waste of coal and also concerning what may be termed the "scientific side of the chemistry of combustion," featuring fuel analysis and refined scientific operation of boiler furnaces, but little about the practical application of the scientific principles of steam generation to the operation of everyday, customary and typical steam plants. This lack, the author endeavors to rectify in the presentation of his subject.

He first concisely but constructively discusses coal, its formation, value and utilization for steam generation, outlining the chemistry of combustion and describing the methods which should be followed in firing boilers. An instructive chapter is devoted to a discussion of types of furnaces, and then the author takes up various questions affecting economical boiler operation—the air supply, composition and regulation of furnace and flue gases, feed-water heating, quality and characteristics of steam—before discussing types and performances of steam boilers. The discussion of the steam generator is brief but well illustrated by examples of well selected apparatus.

The efficient maintenance of boiler plants—cleaning of flues, care of mountings, the proper housing of the plant, etc.—is well brought out and a constructive discussion of brick work settings for boilers, featuring defects and their costly results, is noteworthy. Another section of importance is the chapter devoted to the losses due to radiation of heat and means of mitigating such waste. Steam mains are also given considerable thought and a short but helpful chapter describes the approved examination of a boiler plant for defects and losses.

V. Van Nostrand Co., Mechanical Laboratory Methods, by Julian C. Smallwood, M. E., 423 pages, illustrated, price $3.50.

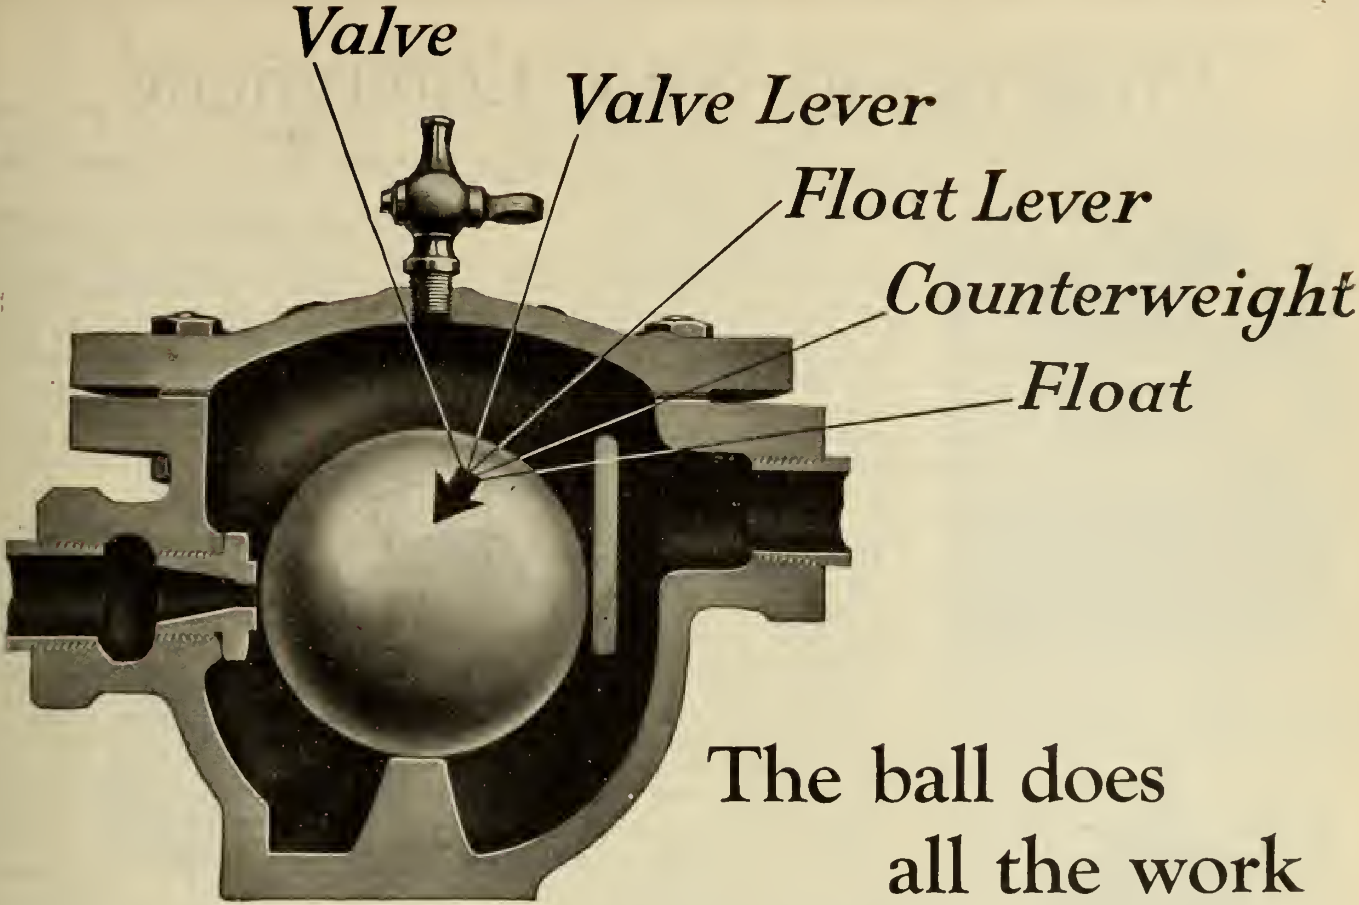
The first of the three sections of this book is devoted to instruments, their errors, methods of calibration and their use. Under this heading various apparatus such as gauges, brakes, indicators, planimeters, meters, thermometers, calorimeters and belt and oil testers are discussed. Looking over these pages in a general way, one is critical of the statement that the slip of a belt may be accurately found by counting the speeds of the driving and driven pulleys, and one wonders what coefficient of contraction means when applied to a weir.

The next part of the book, containing about forty pages, deals with fuels and their composition and the methods of calculating their heating values. It also contains data for estimating and measuring the products of combustion.

The last 160 pages deal with the testing of power plant units including steam engines, steam pumps, boilers and auxiliaries, gas engines, refrigerating machines, air machinery, water motors, electric motors, and miscellaneous machines. As the space occupied suggests, this subject has been treated quite fully and in accordance with the latest rules, so that the discussion will be found helpful.

Genius isn't nearly so valuable in a power plant as common sense.

It isn't a bit queer that efficient plants are invariably clean plants.



IT would be impossible to make an efficient steam trap with fewer parts than those used in the Johns-Manville Trap. There are only three parts—the rolling ball, the discharge bushing and the body—the ball is the *only* moving part.

The ball does all the work

THIS is a cross section of the Johns-Manville Steam Trap. All the usual complexity of steam trap mechanism is simplified into just one moving part—a hollow copper ball.

It is so simple that it cannot get out of order, which gives it a reliability that is making thousands of satisfied users come back for more. It is a trap that you can install and forget—for it needs only the occasional inspection that any good piece of machinery deserves.

The Johns-Manville Steam Trap starts cold, discharges both water *and air*, and absolutely prevents steam leakage.

The trap is light and small, yet with no sacrifice of capacity. There are no adjustments. Its cost is low.

Investigate the Johns-Manville Steam Trap in the engineering way—test one.

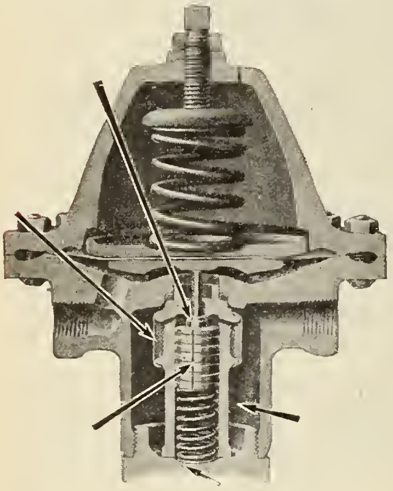
Progress in New Equipment

Cash Reducing Valves

A pressure reducing and regulating valve equipped with a self-contained strainer placed close to the valve seat is believed by the manufacturers, A. W. Cash Co., 214 McLelland Bldg., Toronto, to insure more accurate operation, increase the life of the wearing parts and obviate the necessity and expense of installing a separate strainer on the inlet line.

Steam at initial pressure entering the regulator on the inlet side passes through the strainer, which precipitates all but the finer particles of foreign substance to the sediment chamber below. It then flows through a series of inlet ports, passes on through the seat opening, through the diaphragm chamber, and through the outlet side into the delivery or working pressure line.



Assume that the initial pressure is 100 lbs. and that the valve is set to deliver 40 lbs. As soon as the delivery pressure exceeds 40 lbs., its action on the under side of the diaphragm will raise the diaphragm spring and permit the valve proper to close, or to restrict itself to the point where proper reduction is effected. When the delivery pressure falls, the action of the diaphragm spring will force the valve open to the proper point to restore the required reduction.

W-S-M Gas Producers

The mechanical gas producer as distinguished from the hand-poked, hand fed stationary type has come to be recognized in the gas-making industry as one of the most efficient types of apparatus for making producer gas from coal. The W-S-M Gas Producer Type L No. 8 designed by the Wellman-Seaver-Morgan Co., of Cleveland, Ohio, will be manufactured at an early date in Canada by the John Inglis Co., 14 Strachan Ave., Toronto.

The generally accepted rating of a gas producer is the pounds of coal it can gasify per hour. The W.S.M. producer has an efficient gasifying capacity from 1500 to 2750 lbs. of bituminous gas coal per hour. The most desirable fuel is a bituminous coal of the following composition:

Volatile matter	30% to 40%
Fixed Carbon	50% to 60%
Ash under	15%
Ash fusing at	2200° F. or over.

Using coal of this quality, the producer has an over-load capacity of over 3600 pounds.

The producer is fitted with a mechanical coal feed. It consists in the main of two principal elements. The upper or measuring wheel is rotated at a variable speed whereby the rate of coal delivery is regulated to the demand for gas, and at the same time the coal is measured.

The direction of rotation is against the descending coal, which tends to lift it and prevents choking in the spout from the bin. The lower revolving drum delivers the coal to the producer. The feed is operated by a rock shaft having an intermittent motion. Adjustment is obtained by a handwheel attached to a screw nut by which the length of the driving lever is altered.

A safety device is provided to prevent breakage in case of an obstruction becoming wedged in the distributor. The feed is provided with a hand operated coal gate located in the upper part of the feed case, and serves to shut off the supply when desired.

In each base, two cleaning holes are placed for cleaning deposits of tar and soot which may tend to choke the coal delivery.

How McClary's Get Power

ONE of the cleanest and most compact in the country. This is the reputation that has been earned by the power plant of the McClary Mfg. Co., London.

This achievement is attained in a large way by the fact that the power for McClary's is obtained from hydro, while a second means is the fact that they have a man like George E. Moll, the industrious chief mechanic, who has been in charge of the power plant for no less than 20 years. Previous to joining the forces of McClary's as chief engineer, Mr. Moll was a locomotive engineer—starting as a cleaner and moving up to fireman and engineer. The chief engineer holds the opinion that cleanliness is one of the essentials of a good power house and his plant is one of the best.

Should the Hydro service be interrupted, the plant is equipped with a 300 h.p. vertical compound high speed Leonard engine. This engine is connected direct to a Westinghouse generator of 550 volts capacity. The steam is generated by four Leonard boilers of 125 h.p. each, consuming 11 tons of coal every 24 hrs. These boilers work continuously at 115 pounds pressure.

Two duplex air compressors, one high and the other low pressure, give the necessary pressure for spraying enamel, air lifts and atomizing oil for the oil burners. Six enamel ovens are heated to 1,000 degrees by the use of fuel oil. The plant is equipped throughout with water sprinklers for fire prevention. Equipment includes pumps capable of pumping 1,000 gallons of water per minute, and the plant reservoir has a capacity of 197,000 gallons of water. The pumps are so arranged that they can pump from the large Webster heater, capacity 500 h.p., or water can be pumped from the reservoir to the boilers.

Mr. Moll has a staff of four engineers and three firemen and claims that engineers should be graded according to their plant and the salary should also be stipulated in ratio to the capacity of the power house. This chief engineer states that he would far rather have a practical engineer than a man with an overload of technical knowledge only.

DISCHARGING OIL TANKERS

For the purpose of discharging oil from tank vessels it is necessary to arrange some flexible connection between the tanker and the barge which is being filled. As a rule rubber or metallic hose is employed for this purpose, but both types are liable to burst as a result of chafing in use. This drawback had led to the development of mechanical steel pipes with flexible joints, and in this type of appliance a British firm has introduced a notable development. It is based upon what is called a "divided pipe joint," which was designed and made by this firm some years ago in connection with fire floats.

AIR COMPRESSOR BULLETIN

The Canadian Ingersoll-Rand Co., have issued a bulletin K-311, on the class ED-1 air compressors. This line of compressors is manufactured entirely at the Sherbrooke, Que., plant, and are of the power-driven, single-stage, straight-line type. The bulletin gives complete details of the construction of the compressors, and is well illustrated.

REFRIGERATION

(Continued from page 22)

compression refrigerating system the total heat taken up is equal to the heat absorbed in the refrigerator plus the heat equivalent of the mechanical work done upon the medium in the compressor. The former has been shown to be 474.3 B.t.u. and the latter 99.3 B.t.u.; therefore the heat rejected to the cooling water = 573.6 per lb. of ammonia circulated.

Ton of Rèfrigeration

When the steam engine was first invented it was used as a locomotive, and as horses had until then been used for traction purposes, steam engines were naturally rated in horse-power capacities, the mechanical horse-power being soon established as equal to work done at the rate of 33,000 ft. lb. per minute. Prior to the advent of the refrigerating machine natural ice had been used for cooling and it followed as a matter of convenience to rate refrigerating machines in tons of ice melting capacity. Taking the latent heat of fusion of ice at 144 B.t.u., the quantity of heat absorbed by the melting of one ton at 32 deg. F. is

$$2{,}240 \times 144 = 322{,}560 \text{ B.t.u.}$$

A refrigerating machine capable of performing this amount of effective work per day of twenty-four hours continuous operation is rated as a one ton machine, and a commercial ton of refrigeration is therefore at the rate of 322,560 B.t.u. per day, or 13,440 B.t.u. per hour, or 224 B.t.u. per minute. A plant capable of performing useful work at the rate of 322,560 B.t.u. per hour, would, of course, be rated at a 24 ton machine.

Horse Power Per Ton

It has been shown that the amount of useful work performed in the refrigerator per lb. of ammonia circulated is, under the conditions set forth, 474.3. B.t.u., therefore the quantity of ammonia to be calculated in order to produce a refrigerating effect of one commercial ton is

$$322{,}560 \div 47.3 = 680 \text{ lb. per day.}$$
$$= 28.3 \text{ lb. per hour.}$$
$$= 0.472 \text{ lb. per minute.}$$

It has also been shown that the heat equivalent of the external work performed on each lb. of ammonia handled by the compressor is 99.3 B.t.u., therefore the heat equivalent of the external work per commercial ton of refrigeration is

$$99.3 \times .472 = 46.87 \text{ B.t.u.}$$

If the volumetric efficiency of the compressor (V.E. being the ratio of the actual weight of ammonia pumped per unit of time to the amount calculated from the piston displacement) were 100 per cent. it can readily be shown from the foregoing that the compressor horsepower per ton of refrigeration would be 1.10.

Since, however, the volumetric efficiency of vertical single-acting machines operating under the standard gauge pressures of 19.6 lb. and 155 lb. is approximately 84 per cent., the compressor indicated horse-power becomes,

$$\text{c.h.p.} = \frac{46.87 \times 777.5}{33000 \times .84} = 1.315$$

The quantity 777.5 is the mechanical equivalent in ft. lb. of one B.t.u. and the resultant horse-power is based on the assumption that compression is adiabatic. In practice, however, the compression curve falls away from the adiabatic with the result that the mean effective pressure is decreased, so that the actual c.h.p. becomes approximately 1.26 per ton of refrigeration.

As knowledge is sought in the power house, laboratory, office and factory, the twin brother of the teacher—the editor—must perform his valued function. Sharing of knowledge is characteristic of human progress which could not long thrive without the mediums of exchange of thought and experience afforded by the activity of the editor.

The volumetric efficiency of horizontal double-acting machines is about 7 per cent. less than for single acting machines but the c.h.p. per ton of refrigeration is not materially increased thereby because the piston rod of the former type of machine accounts for about 5 per cent. of the difference in efficiency while the remaining 2 per cent is accounted for by the extra clearance required—factors which have no bearing on this question. The c.h.p. per ton of refrigeration depends, of course, upon the operating conditions.

GASKET HINTS

(Continued from page 31)

wrench of the correct length is used and then tighten only enough so that the leakage is prevented. Do not tighten too tight. Any further tightening after leakage is stopped simply reduces the elasticity of the gasket and does not give it an opportunity to "breathe" as it should simultaneously with the expansion or contraction of the pipe lines.

I, therefore, regard the matter of tightening as most important of all and want to impress it upon all users of flexible metallic gaskets. By being as careful in tightening the gasket as one is when tightening an ordinary steam engine stuffing box, or when taking up the wear in a bearing, the best results will be obtained. Take it easy. Don't strain muscles, wrenches, bolts, gaskets, or anything. If directions are always carefully followed much labor and fatigue will be avoided.

Copyright, 1923, by Hexitallic Gasket Co., Camden, N. J.

Don't talk efficiency to the big Boss; talk dollars worth of coal saved per year.

Improving Power Plant Efficiency

THERE are three way of improving power-plant efficiency—maintaining the efficiency of the operating cycle, selecting the proper equipment, and improving the equipment by changes in design. Although in coal-burning plants over-all thermal efficiencies of about twenty per cent. have been obtained under favorable conditions, even in the largest plants the average for a year is far below this figure. Fifteen per cent. is about the best that the average large station is doing, with many plants, having ratings for twenty thousand to thirty thousand kilowatts capacity, operating at ten per cent. or less. Instead of producing a kilowatt-hour on seventeen or eighteen thousand British thermal units, the average figure will be from twenty-three thousand to over thirty thousand.

There are many conditions in plant operation that tend to reduce the average over-all efficiency; some of them are controllable and others are not so readily handled. Load factor undoubtedly has an effect, but cases are on record where, in plants of considerable difference in size, the smaller plant operating at about forty per cent. and a larger one at sixty per cent. load factor, the smaller plant showed thirty per cent. less coal consumption per unit output than the larger station. Even though these conditions may exist, taking two plants that alike as to equipment, if both are operated with equal proficiency, the station with the highest load factor will develop the highest over-all average efficiency.

For years it has been possible to obtain an over-all boiler-and-furnace efficiency of over eighty per cent. with large stoker-fired boilers without the use of economizers, yet the average in many of the large plants is down around sixty-five per cent. or less. There are a few exceptions to these figures where efficiencies up to about seventy-seven per cent. have been obtained without the use of economizers. The maintenance of equipment has a marked effect on over-all efficiency and is very largely under the control of the operating force.

The wide difference in average operating efficiencies of two plants under similar conditions can be attributed to operating methods and the selection of the kind and size of equipment to serve the load. When selecting equipment, it is not always possible to obtain the arrangement that will give the highest over-all efficiency, or engineers have not felt justified in doing so.

While power-plant engineers are waiting for the higher economy to be obtained from new designs, the present differences between the average over-all plant efficiency and that which can be obtained with present design of apparatus offer a fruitful field for careful study and improvement.

"SAFETY" PLASTIC METALLIC PACKING

Packing in bulk.

This packing is made of an alloy of the FINEST ANTI-FRICTION METALS which, combined with the BEST LUBRICATING MATERIALS which always remain in the packing, make it practically Self-Lubricating and Frictionless. It is

GUARANTEED TO LAST THREE YEARS WITHOUT RENEWAL

In fact there are many Engines, Pumps, Compressors, Expansion Joints, Valves, etc., on which this packing has been in use for over 12 years with the very best satisfaction.

Let us send you further particulars also about our "Safety" Superheat Sheet Packing.

STEEL MILL PACKING CO. - WINDSOR, ONT.

SECTIONAL COVERINGS

Save Coal

by using

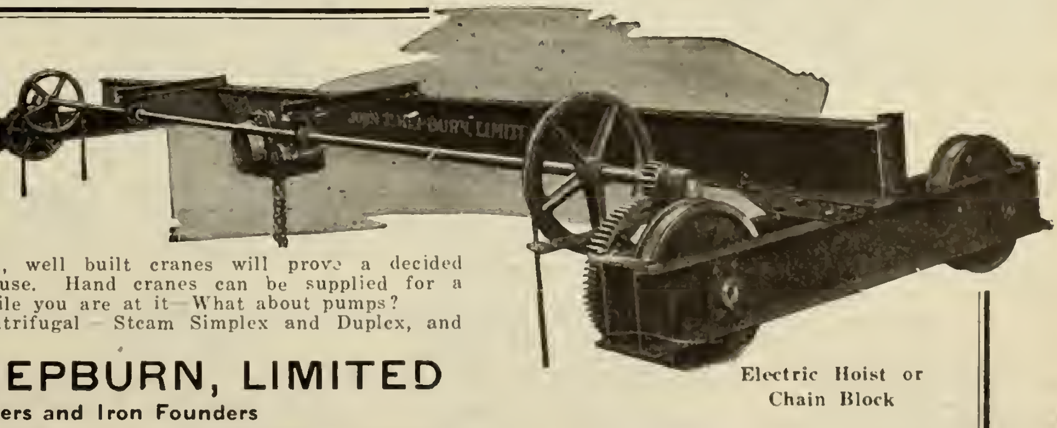
85% Magnesia Sectional Covering

The extra saving in coal (power) and dryness of your steam should decide you in favor of K. & M. "Featherweight" 85 per cent. Magnesia Pipe and Boiler Covering.

Would you like to know just why this widely used boiler covering is the most durable and most efficient fuel conserver of all pipe and boiler coverings? Then send for free booklet. It contains much valuable information for engineers.

Keasbey & Mattison Co., 25 Front St. E., Toronto.

HEPBURN CRANES



These easily manipulated, well built cranes will prove a decided saving in the Power House. Hand cranes can be supplied for a moderate outlay. And while you are at it—What about pumps?
We make all kinds—Centrifugal—Steam Simplex and Duplex, and Power Pumps.

DEPENDABLE WRENCHES

Williams' line of "W. & B." Screw Wrenches are strong, sturdy, dependable tools.

Machinists' Knife Handle and "Railroad Special" Wrenches are recommended for the heaviest service; 7 sizes; 6 to 21 inches.

Agricultural Wrenches meet the demand for a good tool at a moderate price. 5 sizes; 6 to 15 inches.

J. H. WILLIAMS & CO., Limited
"The Wrench People"
78 Thorold Road St. Catharines, Ontario

SONDERGLASS

"The Unbreakable Boiler Gauge Glass"

Two Glass Tubes in One

The different metals used allow for expansion and changes of temperature to which the glass is subjected, and add greatly to its pressure-resisting qualities, as each of these metals has different degrees of expansion. The inside of the tube expands in proportion to the temperature of the steam or hot water and the outside according to the temperature of the air.

Why FIBRICO JOINTLESS FURNACE LINING **is better than fire brick—**

This plastic, jointless furnace lining is better than fire brick because:

1. It is jointless.
2. It is plastic.
3. It is air and gas tight.
4. It will stand 3100° F.
5. It will save fuel.
6. It can be installed by inexperienced labor.
7. It will outlast fire brick.
8. It can be used in any boiler, furnace or oven.
9. It can be used where ever fire brick is used.
10. It cannot be excelled for patching broken and burned out linings.

JOINTLESS FIRE BRICK CO

1142 Clay Street, Chicago, Ill.

DISTRIBUTORS: Beveridge Supply Co., Ltd., Montreal; Shell Bar Boico Supply Co., Ltd., Toronto; Evans, Coleman and Evans, Vancouver, B.C.; Winnipeg, Supply and Fuel Co., Winnipeg; Gorman's, Ltd., Calgary, Alta.

De Laval Oil Purifier

The Commonwealth Edison Company, of Chicago, Ill., rely upon De Laval Oil Purifiers as the sole means of removing water and sludge from the lubricating systems of the 3000 kw. turbo-generators in their new Calumet Station. The De Laval Purifier at Calumet is shown at the side.

Additional De Lavals are used to purify lubricating oil in the other stations of this Company, and several De Laval Transformer Oil Purifiers are also operated.

Spring Repairs

Overhaul and repair your buildings before the Spring Rains and the Spring Sun find the weak spots in them.

ROOFING — Rubber, Plastic and Liquid. Also Sheathings, Wall-board, etc.
ROCKFACE — White Water Paint, easily applied and inexpensive. Will not flake or peel off. Wood or Masonry.
PLIBRICO—Jointless Fire Brick for putting your furnace linings back into shape, after the strain of the winter months.

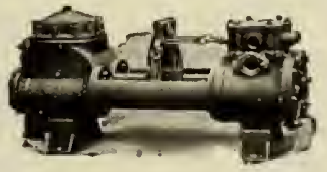
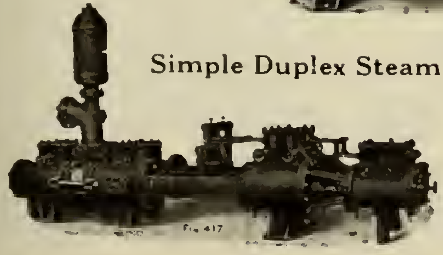
Builders of Pumping Machinery

Our 70 years' experience in designing and manufacturing pumping machinery places us in a position to analyze any situation and make recommendations as to the type best suited for same.

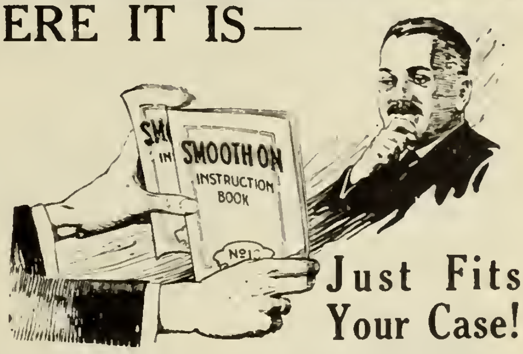




Simple Duplex Steam Power for all conditions of Service.

SMOOTH-ON IRON CEMENTS

HERE IT IS—



Just Fits Your Case!

Many engineers have learned from experience not to say, "That will have to come down for repairs," until after they have tried Smooth-On Cements. For Smooth-On saves dismantling in a large proportion of cases.

SMOOTH-ON
Instruction Book No. 19

Just off the press, contains 144 pages of engineering information and shows many instances of how time and money were saved by engineers through the use of Smooth-On Cements for making power plant repairs. This book shows you "how it is done" quickly and economically without dismantling machinery or pipe lines. Write today for your copy —IT'S FREE.

Smooth-On Cements are sold in 5-lb., 10-lb., and 25-lb. tins; also in larger sizes.

Building a one-piece furnace lining without special forms.

BETSON'S PLASTIC FIRE BRICK

REG. U.S. TRADE MARK PAT. OFF.

Makes practicable, solid, one-piece furnace linings, including front and back arches, side walls and baffles. It costs but little to install in any make or type of boiler. It saves fuel, annoying shut-downs, costly repairs, and increases the amount of power from the fuel used.

Complete details of the many uses, methods of installing, how to order, measurement blanks, etc., are contained in a booklet of information which we will gladly send you. Tell us the individual to whom it should be addressed.

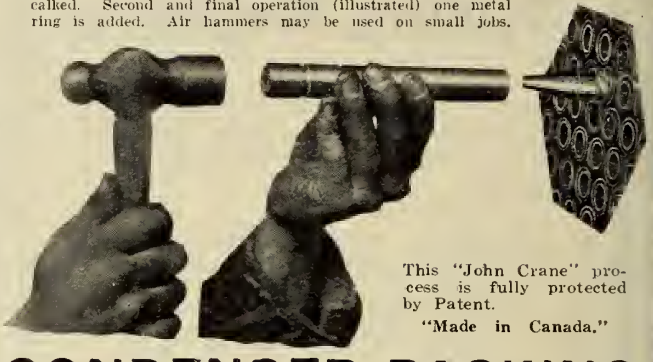
A COMPLETE SERVICE IN

"John Crane"

FLEXIBLE METALLIC PACKING

First, one metal and two expansion rings are pushed in and calked. Second and final operation (illustrated) one metal ring is added. Air hammers may be used on small jobs.



This "John Crane" process is fully protected by Patent.

"Made in Canada."

CONDENSER PACKING

John Crane Metallic packing for Condensers holds the tubes firmly but without a crushing grip. It permits lateral expansion and contraction of tubes overcoming destructive stresses. Eliminates electrolytic decomposition of tube ends. Easy to apply and very durable.

The class of engineers who are taking to this process speaks for its value.

Investigate! Full data upon request.

SMOOTH JOURNALS KEPT SMOOTH

A lining of Magnolia Anti-Friction Metal never squashes out of a properly designed bearing, yet is soft enough to let dirt and grit sink in below the critical surface, instead of cutting the journal in trying to push the contact surfaces apart. That this positive protection is actually present and does not appreciably diminish the anti-frictional qualities of the bearing, has been thoroughly established. Long life has characterized Magnolia anti-friction metal bearings in cement plants, brick yards, etc., where other bearing metals proved themselves to be costly luxuries.

Insist to your dealer that only Magnolia Anti-Friction Metal will be accepted and you will soon be able to see its superiority.

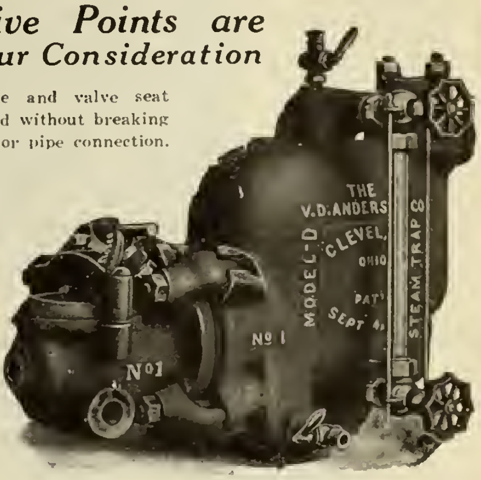
ANDERSON MODEL "D" STEAM TRAP

These Five Points are Worth Your Consideration



1. Both the valve and valve seat can be removed without breaking a steam joint or pipe connection.
2. The valve is always sealed with at least three inches of water, making the escape of live steam impossible. The strainer and sediment chamber prevent sediment or scale getting into the valve.
3. A glass water gauge fitted to the trap makes it possible to ascertain at a glance whether the trap is working properly.
4. Made for high or low pressure or exhaust steam. Will lift water against back pressure 5 lbs. less than pressure of trap.
5. Built of best possible materials for the purpose. Every part interchangeable.

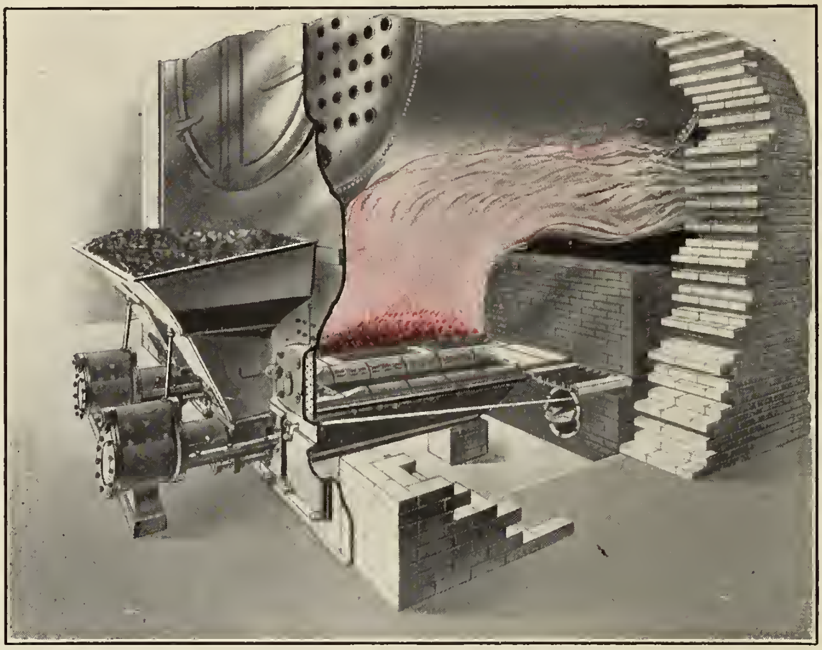
AMERICAN
STEAM ASH CONVEYORS

MACLEAN STOKERS

Save Fuel

Eliminate Smoke

Easy to Install



Save Labor

Reduce Upkeep

Easy to Operate

IT IS a remarkable fact that although the power house lends itself to far greater profit-making economies from relatively small investments than any other department of the average industrial plant, it is often the most neglected.

The importance of boiler room efficiency at minimum costs can be appreciated only in its relation to dependent operations in other departments and as a burden on the ultimate production cost.

The MacLean Underfeed Stoker is scientifically designed and built to take care of this problem.

It starts right in to save money from the day it is installed.

Working automatically, it feeds the fire just the right amount of coal, varying the feed in accordance to varying demands for steam. In this way a constantly uniform steam pressure is maintained regardless of sudden load fluctuations.

It burns all classes of bituminous coal. There are no siftings of unburned coal to the ashpit because there are no grates. Easy to install, easy to operate, it is adaptable to practically every type of boiler and all classes of steam plants.

Let us estimate the savings to be made in your plant. No obligations whatever.

DESIGNED BUILT AND CONTROLLED BY CANADIANS

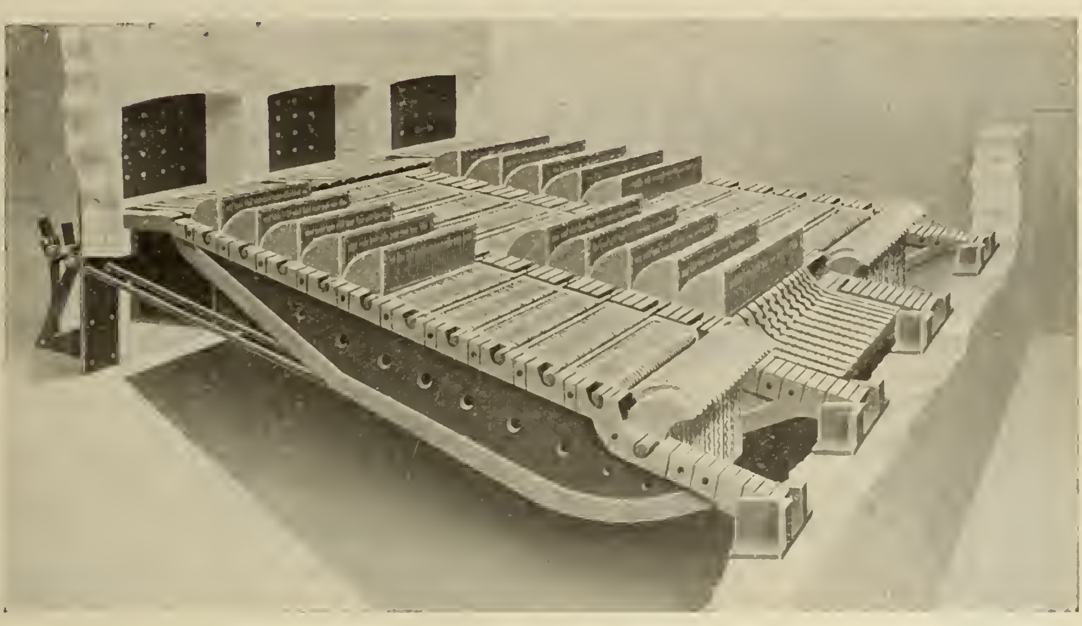
The Coal it Saves—Soon Pays its Cost



THE FILES STOKER

Pays for Itself in One Year

Below is a copy of one of the many letters we have received, telling of the efficiency and economy of the Files Hand-Operated Stoker

Re FILES HAND STOKERS.

Gentlemen:—

Frequently we receive letters from manufacturers, asking for information and our experience with the "Files Hand Stokers"—the most economical and efficient system of burning coal with the utmost conservation of labor.

As these inquiries are becoming more and more frequent, our better plan will be to furnish you with a letter to pass on, outlining our experience and satisfaction.

In September, 1920, we placed an order with you for two 150 H.P. Tubular Boilers, specifying our desire to have them equipped with "Files Hand Stokers." This we did on the recommendation of our United States Engineering Department, who had installed "Files Hand Stokers" in some seventeen plants, finding in them a decided saving and advantage over flat or shaking grates.

Speaking for ourselves, we have found them most satisfactory and economical, particularly so in regard to the elimination of smoke, rapid disposal of ash and clinker, thorough cleaning of fires without disturbing the active fire, and in maintaining an even bed of fuel.

We are able to keep a clean fire at all times; we have no cleaning period, for with the "Files Hand Stoker" the grate can be cleaned at peak load. It is only a matter of working one rod on each section, which can be done in less than two minutes.

The better the coal the better the result, but almost any kind of coal that will burn free can be used. With good coal, however, it is an easy matter to procure 150% boiler rating, which in reality is 12½ lbs. evaporation per pound of coal. Generally speaking, evaporation is around 7 or 8 lbs., and often as low as 5 or 6 lbs.

Our Files Hand Stokers have now been installed about two years, during which time they have paid for themselves twice over if we consider the saving in fuel.

And what we have done and are doing with them others can do.

We know they effect a saving; we know they are a convenience; they have proved satisfactory in every particular, and we have no hesitation in recommending them.

Yours very truly,

THE MERIDEN BRITANNIA CO., LIMITED.

LUNKENHEIMER

Bronze Gate Valves

Due to correct design, the use of only the best materials procurable, and skilled workmanship, long and satisfactory service is assured. Longevity of the Valves as a whole is further enhanced by renewability of any worn or broken parts.

The extensive line of Lunkenheimer Gate Valves permit of a selection for any specific purpose and for general prevailing pressures, making possible the standardization of these Valves throughout the plant with the resultant assurance of satisfactory service and economy of maintenance.

Catalog 58DC portrays the entire line. A copy will be sent upon request.

SARCO

Products that Increase Efficiency and Cut Costs

STEAM TRAP SARCO. Costing only one-third as much as "float" traps, the Sarco enables you to trap every point where condensation forms, thereby saving steam and fuel. No installation expense—fits into the line like an elbow, Has only one moving part—nothing to get out of order or require adjustment. Will not air bind. Booklet J-35 on request.

RADIATOR TRAP SARCO. A highly sensitive, factory-adjusted trap that keeps steam lines free from condensation. No water hammer or air binding. Maximum closing pressure — will not leak. Line contact between the cone and seat prevents scale deposit. Easy to clean. Exceptionally heavy construction. For vacuum, vapor and low-pressure steam heating systems. Write for Booklet J-109.

SARCO TEMPERATURE REGULATOR. Self-contained and automatic. Does not require electricity, compressed air or water. No rubber or leather diaphragms to give trouble. Factory-calibrated for desired range. Operates on steam, water and gas valves. Positive in action. Send for Booklet J-74.

SARCO INDICATING THERMOMETER. Manufactured under the famous Fournier patents, by expert thermometer makers in our own laboratories. Dial may be placed any distance from the sensitive bulb up to 500 feet or more. Indicates temperature of bulb only. For any desired range from minus 90° F. to plus 3000° F. Booklet J-153 on request.

SARCO STRAINER. For use in any installation where it is necessary to protect valves or other parts against the action of scale, sediment, etc. The large sieve area insures thorough straining without interruption of flow. Can be placed in horizontal or vertical lines, or at any angle. Blow-off connection permits cleaning strainer by simply opening valve. Quickly taken apart and reassembled. Ask for Booklet J-201.

Any Sarco Instrument sent on trial for 30 days.

Fisher Pressure Regulator.
(Type 90.)

A Money-Saver—WHY?

1. Because Fisher Pressure Regulator, Type 90, delivers to an operation or process exactly the amount of low pressure required—no more—no less. It maintains the desired low pressure without fluctuation, regardless of variations in high pressure.

2. When an operation or process is interrupted, this valve automatically cuts off the low pressure and remains closed until the demand at that point is renewed, when it automatically releases just the required low pressure.

Thousands are in use for curing, drying, bleaching, dyeing, vulcanizing, evaporating and similar processes in textile mills, cotton seed oil mills, sugar refineries, tobacco and rubber plants, lumber mills, etc.

Fisher Pressure Regulator, Type 90, saves enough to pay for itself in a very short time.

Send for Bulletin 210, which gives complete information about this wonderful valve.

Flue gases can be reduced 50 degrees by careful firing and clean boiler surfaces

Such is the substantial saving that can be effected by recording and measuring your flue gas temperature with

TRADE MARK
BRISTOL'S
REG. U. S. PAT. OFFICE.
Recording Pyrometers

Of course, the temperature of outgoing gases can be decreased by economizers, or by a change in the baffling — but such changes are costly and the economy depends upon the cost of coal.

The information supplied by Bristol's Pyrometers, as to the temperature of uptake gases leaving the boilers, is of prime importance as an aid to super-efficient plant operation.

Hundreds of Bristol's Pyrometers are recording flue gas temperatures in prominent power plants. Let us tell you more about what they could do in your plant. Our new Catalog O-1401 is waiting for your address.

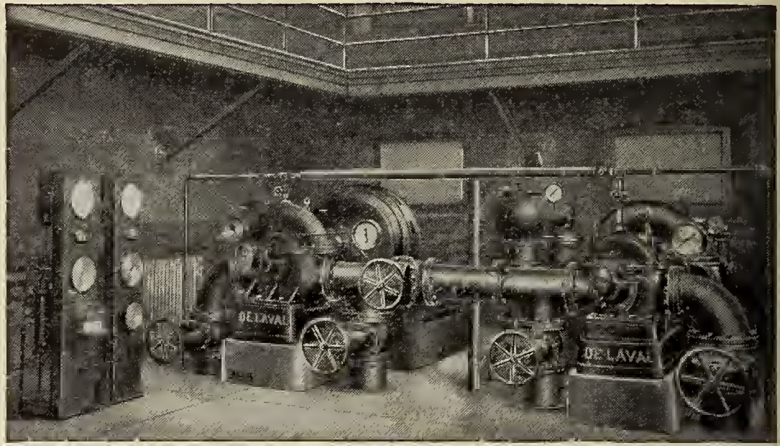
BROCKVILLE USES ELECTRIC PUMPS

WITH STEAM AUXILIARIES



As shown in the photograph, the two De Laval pumps supplying water to Brockville, Ont., are so arranged that either one or the other can be used, or the two pumps can be operated in either series or parallel, as required. The construction of the De Laval centrifugal pump insures high maintained efficiency, due to the fact that all parts subject to wear are easily renewable, being manufactured to limit gages on an interchangeable basis. The labyrinth wearing rings in particular, which prevent leakage from the discharge back to the suction, are superior to ordinary flat wearing rings both in effectiveness and in durability, assuming equal clearance in both cases. De Laval centrifugal pumps have shown unimpaired efficiency after four years' continuous use, pumping Mississippi River water. They have other features which recommend them for electric driven plants, including low starting torque, power limiting characteristic, and high average efficiency over a wide range of load. If you are interested in pumping water by steam, electricity, water power or internal combustion engines, ask for our Catalog B-100.

STEEL BELT LACING

Setting New Standards in Belting Performances

BELTS give longer uninterrupted service when laced with Alligator Steel Belt Lacing for Alligator is the strongest and most durable of all belt lacings. It is scientifically and practically correct.

Every Alligator tooth is a vise, clinching around the belt fibers, holding them in equal permanent service.

Practically all authorities on belt transmission recommend Alligator. It is in use every day on millions of belts of every type and size and in every service. Sold at wholesale and retail the world over.

Flexible Steel Lacing Company
4667 **Lexington Street, Chicago**
In England at 135 Finsbury Pavement, London, E. C, 2

From the Standpoint of Science

Alligator teeth penetrate lengthwise of the belt leaving the long burden bearing fibers intact. Each tooth clinches down over its group of fibers, compressing them firmly so that there is no internal friction and wear at the belt end. Likewise the sectional steel hinge pin eliminates wear, the smooth oval faces rocking against each other.

Keep these vital features in mind when you buy belt lacing for the cost of any lacing is nothing as compared to the cost of the belt on which it serves.

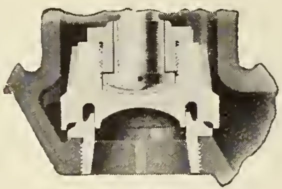
EDWARD VALVES

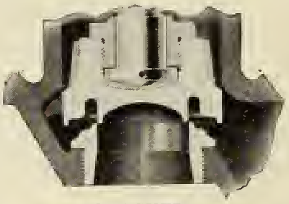
Note the Protection against Cutting Action



CLOSED

Unless positive means of prevention is provided, the cutting from wire drawing between the seat and disc of a valve will rapidly destroy the seating surfaces. This is especially true under high pressures and temperatures, where very small leaks will rapidly grow on account of the terrific erosive action, making the life of the valve very short and increasing the upkeep cost due to frequent repairs and renewals.

In the "cracked" position, the erosive action of the steam is greatest due to the fact that the steam is being wire drawn through a very small orifice and its velocity thus greatly increased. The illustrations show the positive protection which the Edward Protected Seat and Disc affords against this cutting action. Note that in the "cracked" position the seating surfaces are widely separated and protected from the direct flow of steam and that the velocity across the seating surfaces is greatly reduced.



CRACKED

THE EDWARD PROTECTED SEAT and DISC

shown here, insures absolute protection of the most vital organ of the valve, the seating surface.

"A Blessing to Society"

MORE than 85% of our population live in cities of 10,000 or more, and are mainly dependent upon the cold storage industry for their food supply. Impelled by public demand, the increase in storage space is enormous.

October 1, 1922, there were approximately 560,000,000 cubic feet in use in the nation—Chicago alone having more than 227,000,000 and New York following with 118,000,000 cubic feet. In such manner do we grow!

Thus, in line with the modern demand for perfection of details, the House of Jamison had devoted 17 years to the betterment of a complete line of specialized and standardized Insulated Doors, Windows and Ice Chutes.

You must recognize that "Your plant is only as good as your door"—a fact which explains the popular demand for Jamison Doors, recognized as unequalled in strength, sturdiness, simplicity, fitness, long life and ease of operation.

Write for Booklet

Every plant owner and plant builder will find some very pertinent facts in this Booklet. Write for it—marking your request, "Desk," Please.

> *"The cold storage house is a blessing to society. It permits the safe storage of food in times of flush production and holds it for public use during non-productive seasons; and the conduct of such establishments is safeguarded by law."*

Detroit V-Type Stokers for Efficient and Economical Boiler Operation

Frankford Arsenal. U. S. Government War Department. Ten Stirling Boilers Fired by Detroit Natural Draft Stokers. 3000 Horsepower

You profit in many ways by the installation of Detroit Natural Draft Stokers.

First, You can use lower grades of fuel with Detroit Stokers than can be burned successfully by hand firing. Under favorable conditions these savings may run from a dollar to a dollar and a half a ton.

Second, You can save labor if you have a number of boilers. One man can tend a very much greater horse-power of stoker-fired boilers than hand-fired.

Third, You secure high over-all boiler efficiencies. Average hand-firing practice shows 55 to 60% boiler efficiency. The average boiler efficiency secured by users of Detroit V-Type Stoker is 70 to 75%.

The United States Government has found Detroit Natural Draft Stokers to be satisfactory, efficient and economical. Over 14,000 boiler H.P. are served by Detroit V-Type Stokers in Government institutions such as:

St. Elizabeth's Hospital, Washington, D. C.	3600 H. P.
Federal Reserve Bank, Cleveland, Ohio	1200 H. P.
Edgewood Arsenal, Edgewood, Maryland	4000 H. P.
U. S. Marine Barracks, Paris Island, S. C.	1000 H. P.
Camp Perry Proving Grounds, Camp Perry, Ohio	1800 H. P.
U. S. Naval Hospital, Brooklyn, N. Y.	1330 H. P.

For economy's sake you should install Detroit Stokers under your boilers. Remember there is a machine for every purpose — V-Type Overfeed for natural draft — Single Retort Underfeed for forced draft with boilers up to 250 H. P.—Multiple Retort Underfeed for large boilers.

Send for your copy of the Detroit V-Type Stoker Bulletin No. 338. It is yours for the asking

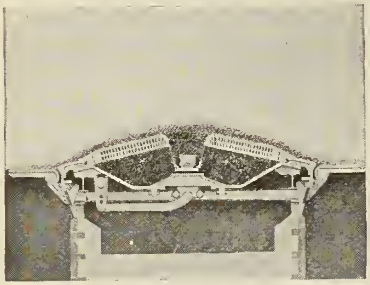
SAVE FUEL "V" AND LABOR

DETROIT TYPE STOKER

It fulfills conditions met by no other stoker—



(Sectional View)

THE *"Lateral Retort"* Stoker should not be considered either as a substitute for, or an improvement on, the multiple retort type of stoker. It is rather a new type of multiple retort stoker—a type that makes multiple retort stoking possible in many plants that otherwise would be compelled to install an inferior type of stoker.

By embodying a multiple retort arrangement in a single stoker that follows the general design of simple side-cleaning stokers, a number of problems are solved in a remarkably simple way.

For instance, the necessity for basement ash pits is eliminated, since an excavation of 6 to 18 inches provides sufficient space for the two pits into which the ashes are discharged by the simple, side-dump plates. This greatly reduces installation cost and makes the *"Lateral Retort"* Stoker highly adaptable to old boilers in existing plants. Moreover, since the stoker is set very low, ample combustion space is insured when it is placed under low set boilers. Thus in many ways the *"Lateral Retort"* Stoker stands alone. It is the only side-cleaning stoker in which the coal is underfed throughout, giving the greater fuel economy and overload capacity of multiple retort stoking; and therefore it is the one moderate priced, economically installed stoker that in any way rivals the multiple retort type.

Conditions met by no other stoker. Are they your conditions? The catalog will help you decide.

POWER HOUSE

ESTABLISHED 1907 *Toronto, April 20, 1923* A SEMI-MONTHLY NEWSPAPER

Profits Mechanical Stokers Pay Power Plants Daily

Smokeless Combustion From 1685 to 1923, Emphasizing the Dividends Stokers Return While Working Better Than Mere Man Ever Did With His Shovel

THE modern mechanical stoker is a substitute for the human stoker but its purpose is not merely to take the place of the man with the shovel but to effect a number of specific economies in the combustion of coal while doing the work better.

Among the economies, which are of such magnitude as to make the stoker an extremely profitable investment in power plants of any size, may be emphasized the following:

It operates without opening or shutting the furnace door.

It delivers just the small amount of fresh coal that may be properly added to the fire.

It makes additions of fresh fuel as the demand for steam dictates.

It prepares coal for addition to the fire.

It adds this prepared coal at just the right stage of preparation.

It separates, prior to burning, the volatile part from the coal and thus facilitates general combustion in the furnace.

We have had artificial combustion in the world from the earliest times for there is no period of history so remote that it can be cited as a time when men did not know how to build a fire. Somebody has in fact suggested that man might be defined as the cooking animal. Men know how to use fire; the beasts do not.

Combat Smoke Evil

Curiously enough however, only one of the decided advantages incident to the use of stokers has stood out as an actuating motive in their development through the ages and that is the desire to obtain smokeless combustion.

Complaints against the burning of coal are of very early origin indeed. Ten centuries ago in England smoke was supposed to be injurious to trade, health and complexion, and a host of other evils were attributed to its use.

In 1306 Edward 1 issued a proclamation forbidding the use of coal within a city or its neighborhood, and violators were punished by fine and the destruction of their furnaces. But as these penalties failed to end the "nuisance" a law was passed making the burning of coal a capital offense and permitting its use only in forges.

Cheaper power production is demanded to-day as never before, therefore it is very pertinent at this time to enquire into the efficiency, economy and operation of the mechanical stoker. The author of this article, in the capacity of engineer in charge of scores of installations has personally supervised the initial operation of stokers of different types and therefore it is reasonable to assume that the opinion he expresses of their value furnishes an adequate answer to the query.

When it is considered how lightly the violation of smoke regulations are regarded to-day it seems almost unbelievable that a man should have been executed at the command of King Edward for violating the royal edict.

The idea of feeding fuel to a fire so that the smoke and gases evolved passed through a bed of hot coals, is of very ancient origin for alongside the fireplace of the Athanor or constant furnace used by the alchemists in their laborious attempts to transmute base metals into gold, was a hollow chamber, containing charcoal and closed over by a tight lid. As the fire consumed the coal the charcoal descended and was replenished by it.

Exhibited in 1685

Delasme's base-burning furnace, exhibited by him at St. Germain in 1685, took the form of an inverted siphon, the shorter leg containing a grate and serving as the fire chamber, the longer leg acting as the chimney, the smoke forced through the incandescent fuel in this manner being more or less perfectly burned. The fire was kindled at the top and the chimney was heated by a lamp to create a draft.

In 1796 a William Thompson obtained a patent for consuming smoke by admitting a stream of air behind the bridge wall and four years later the Robertsons decided that it was necessary to admit air over the fire in order to burn the gases completely.

The next interesting development was made in 1816 by Gregsor who conceived the idea of using a multiplicity of bridge walls inside the furnace in order to baffle the gases and cause a more intimate mixture. The inventor later introduced air from the ashpit at the point where the two streams of gas joined. The combined gas flow was then made to pass through another bridge wall and out of the stack.

Patent Records Rich

Technical literature since 1850 is replete with descriptions of various forms of smokeless furnaces and the patent records, especially in the English patent office, are richer still in this particular field. This is undoubtedly due to the fact that it was in England attempts were first made to burn high volatile bituminous coals.

It is obviously difficult to trace all the factors contributing to the development of the stoker which is inseparably bound with the development of the boiler arch and the increase in knowledge of the generation and transmission of heat which naturally led to a better appreciation of the essentials of furnace design and combustion space for various fuels.

In Canada to-day no doubt can exist of the great success of the mechanical stoker of which there are a large number of makes on the market, differing in detail but practically confined to three well known types.

These are the overfeed, the underfeed and the chain grate stokers.

For units of less than 200 h.p. there has also been developed a variety of what might be termed the semi-automatic type, including the sprinkling or throwing types and those equipped with movable bars for shaking the fire bed and in some cases dumping the clinkers and ashes, operated by means of levers worked by the firemen.

Hand Stoking Costly

The great objection to hand stoking, even supposing the fireman is a master of the art is the necessity of continually opening the fire doors and keeping them open while fuel is being fed to the furnace.

The doors have to be opened up to lift the fire from the bars and prevent the formation of clinkers and after the lifting has been done the fuel has to be raked over the top to preserve its even thickness.

Naturally every time these operations are performed cold air rushes into the furnace with an accompanying loss of heat and fuel.

This cleaning of fires is one of the hardest things that a fireman has to contend with and is at best a long process attended with inconvenience and loss. and often, in a hard-pushed plant, with a considerable drop in stream pressure.

A further drawback to handfiring is the necessary limitation in the length of the grates, for a man cannot handle a fire which is more than 5½ ft. long, especially when cleaning time comes.

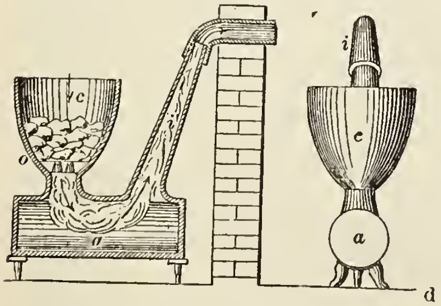
Ends Disadvantages

With mechanical stokers all these disadvantages are removed and a means is provided by which coal can be fed at any required rate, and with the help of forced draft, burned at high rates per square foot of grate surface per hour with much higher efficiency than is possible under any hand conditions.

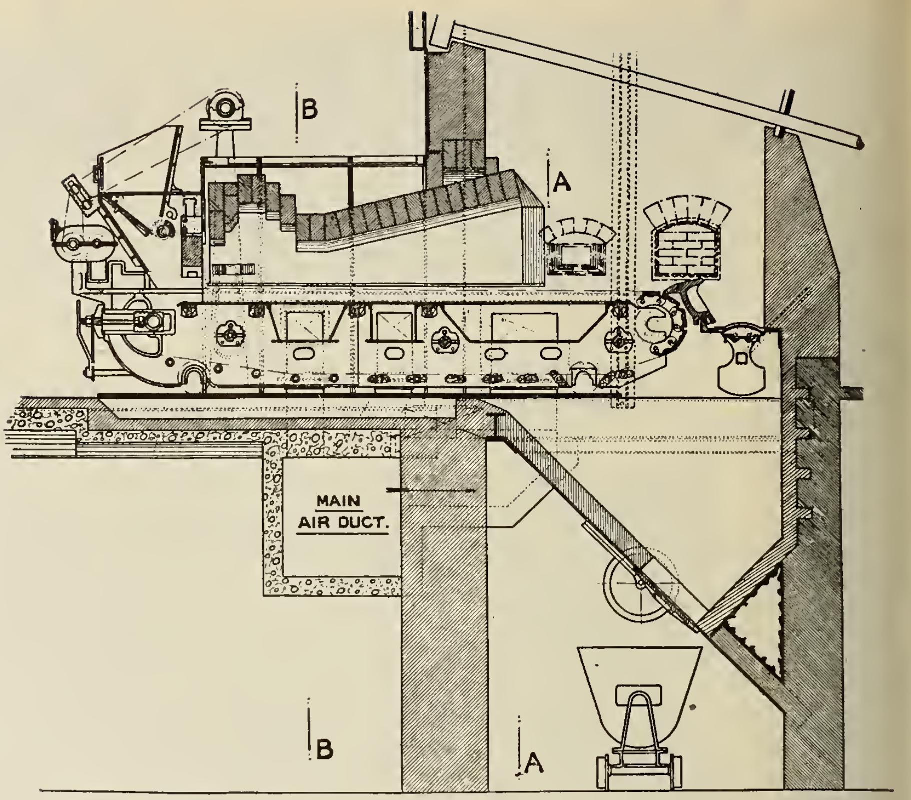
The question of whether to use mechanical stokers of the semi-automatic type can be settled at once by the size of the boiler installation and the characteristics of the load and the type of mechanical stoker selected should be governed by the kind of fuel available and the rating to be developed by the boiler.

Overfeed Stoker Type

Stokers of the overfeed type are of two general classes, the side feed double-inclined or V-type, and the front-feed or single-inclined stoker. The early development of these stokers was along natural-draft lines, because that was the draft available and because it was possible to readily burn all the coal required to meet load conditions.



Base Burning Furnace 1685.



Longitudinal Section Compartment—Type Balanced Draught Chain Grate Stoker.

The double-inclined side-feed stoker was the first to make its appearance on the American continent, Thomas Murphy fathering this particular line of development, commencing about 1875. His first attempt, which was hand-operated, was placed in the firebox of a marine boiler and had inclined grates, every second grate being movable. It was provided with a revolving toothed cylinder or clinker grinder extending from front to rear along the bottom of the V, for the removal of clinker and ash.

Grate Sizes Vary

These stokers to-day are made in various sizes, both as to width and depth, varying from a stoker with a grate surface 4 ft. wide and 3 ft. deep to one having a grate 12 ft. wide and 9 ft. deep.

In the large stokers 1 sq. ft. of projected grate is provided for each 6¼ rated horsepower of the boiler, and in the smaller stokers 1 sq. ft. for about each 5 rated horsepower. Where the stokers are set with a Dutch oven they extend in front of the boiler about the depth of the grate surface of the stoker, this being varied to suit local conditions and the details of the boiler. The overall width of the stoker is roughly the width of the boiler setting.

The head room required will vary with the width of the stoker. The boiler should be set sufficiently high so that the front header or the sill of the tube-door opening clears the top of the arch about 3 in. Where vertical water-tube boilers are used, it is advisable to place a combustion space between the rear of the stoker and the tube surface of the boiler. This can be made of somewhat greater cross-section than that of the stoker. The distance from the rear end of the grate surface to the tube surface should be 6 or 7 ft.

Find Engine Best

Stokers of this class are usually driven by a small steam engine operating the reciprocating bar through a chain of gearing. Where for any reason it is desirable to do so, a motor, either a.c. or d.c., can be used in place of the engine. An engine is preferable to a motor, however, as the exhaust steam which it supplies is useful under the clinker grinder.

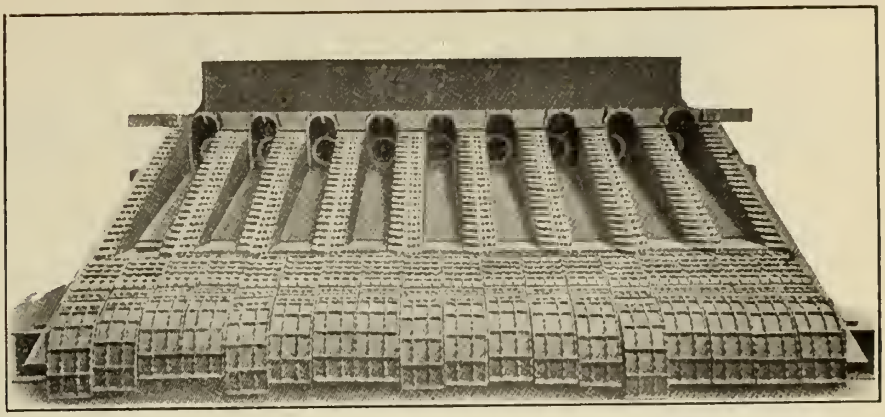
As far as recent developments show, the most convenient and effective means of chilling clinker so that it can be readily handled is by means of low-pressure steam discharged under both the clinker grinder and the lower ends of the grates.

It is desirable that the fuel be fed as uniformly as possible to the stoker. The fuel bed is about 8 to 10 in. thick at the upper end of the grates, thinning down gradually toward the clinker grinder. Minor fluctuations in load should be taken care of by minor variations in the draft over the fire. Where the load changes into a decidedly higher or lower range, the coal feed should be increased or diminished to meet this range, the draft over the fire being regulated to take care of the immediate needs of the boiler.

Draft Loss Varies

The draft loss through the fuel bed will vary with the amount and kind of coal being burned, the high-volatile coals requiring less draft than the lower-volatile coals. The amount of draft required is also affected by the amount and kind of ash which the coal carries.

Where the proper draft is provided, stokers of this class will take care of various loads readily up to 125 or 150 per cent. of boiler rating, although the draft conditions and the grate area are the governing factors in the matter of ratings. Where there is a shortage of draft it is possible to compensate for this in part by increasing the amount of "rousting" or hand manipulation of the fuel bed.

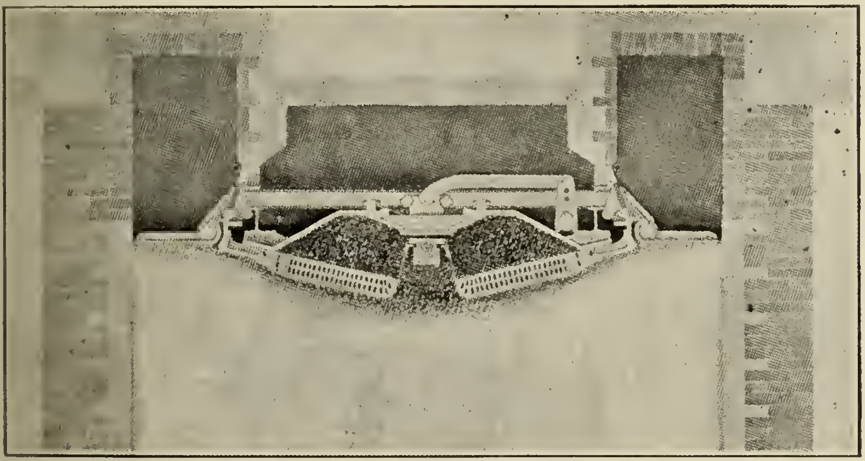


Nine-Retort Self-Dumping Underfeed Stoker.

Add Forced Draft

Where it is desired to obtain more capacity than can be obtained with the natural draft available, it is sometimes possible to do this by adding forced draft. Where forced draft is applied to a stoker of this class, it is advisable to see that all the necessary items for its proper installation are taken care of.

The air should be admitted to the space beneath the grates, either at the front or the rear, in a line parallel with the clinker grinder; two inlets being used, placed symmetrically with reference to the center line of the stoker. Instances have been found where a blower has been placed through each side sheet, discharging air directly against the grates, and troubles have quickly resulted from such practice. Under natural-draft conditions the amount of air reaching the furnace through the openings in the arch plates increases as the capacity increases, and provision should be made so that this same condition holds good under forced-draft conditions.



Multiple Retort Underfeed Side Cleaning Stoker.

Prominent Manufacturers

Among prominent manufacturers of this type of stoker are: The Underfeed Stoker Co., of Canada, "Murphy," York Bldg., Toronto, Ont.; Detroit Stoker Co., "Detroit," 7340 Woodward Ave., Detroit. Mich.; Canada Stoker Co., "Sprinkler," 2 Gould St., Toronto, Ont.; Automatic Furnace Co., Dayton, O.; Westinghouse Electric and Mfg. Co., East Pittsburgh, Pa.

Underfeed Stoker Type

Underfeed stokers are so designed that coal is fed from beneath the burning fuel. This is accomplished by feeding through retorts with adjustments so that the fuel bed is replenished throughout the length of the retort.

The main feed from the coal hopper is accomplished with rams of fixed displacement so that the amount of fuel fed per hour is accurately controlled by regulating the speed at which the rams are operated.

The first development of this type was the single-retort underfeed stoker. This consists essentially of a horizontal retort, into which fuel is fed from the hopper and distributed throughout the length of the retort. Tuyeres are placed around the edge of the retort and through these air is supplied to the fuel under pressure from a fan. Dead plates or dump plates are placed on each side of the retort, from which the ash and refuse are removed.

For wider furnaces, intermediate inclined movable grates or tuyeres are placed between the retorts and the dump plate. These serve the purpose of providing more grate surface and also of depositing the ash and refuse on the dump plate.

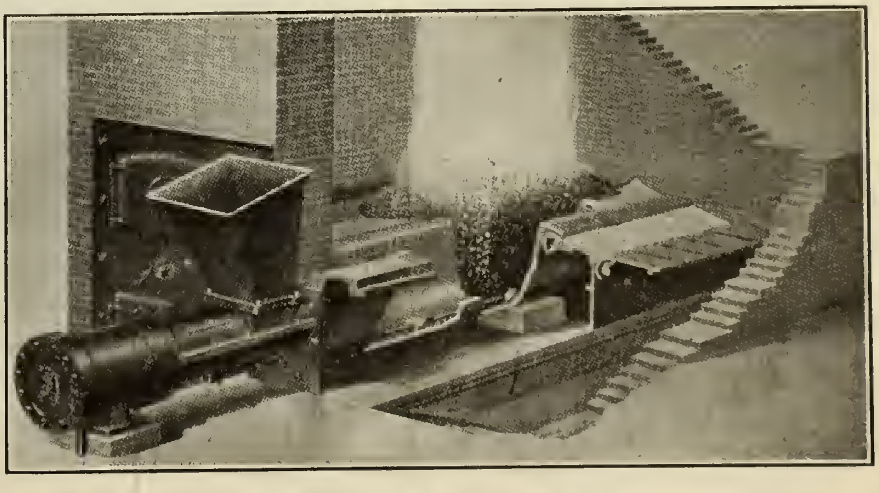
Single-retort underfeed stokers do not require large ashpits and ash tunnels below the boiler-room floor. They are cleaned of ash and refuse by dumping into shallow ashpits which are depressed slightly below the floor line, and withdrawing the ash and refuse through doors in the boiler front at floor level or by withdrawing the ash from the dead plates in the boiler front.

Eliminate Excavation

These stokers are also particularly adaptable to installations in which more than two boilers are placed in a battery, since side doors are not necessary to their operation. Boiler plants may then secure the advantages of the underfeed type of stoker without the expense of excavation and without being limited as regards arrangement of boilers.

Multiple-Retort Stokers

The multiple-retort stoker is a devel-



A Side-Dump Type of Underfeed Stoker.

Chronological History of Stokers, 1819-1923

Traveling and Chain-Grate Stokers.

This Chronological History shows that traveling-grate stokers were introduced earlier than any other type.

1819—Brunton developed a traveling grate which is said to have been the first mechanical stoker brought out in England; it was a circular grate traveling on a vertical spindle.

1834 In the Badmer stoker the grate traveled from the front to the back of the furnace; it was probably the first of its type built.

1841—Jukes may be said to have been the original inventor of the traveling chain grate.

1871—R. F. Weller was the first to manufacture a traveling-grate stoker in America.

1893—Being impressed with the mountains of fine coal that were being dumped along the sides of the mines as a waste product, E. B. Coxe brought out a chain-grate stoker especially designed to burn the small sizes of anthracite, and probably was the first one to use forced draft under a chain-grate stoker. This stoker has been greatly improved upon very considerably and is now manufactured by the Combustion Engineering Corporation. Mr. Coxe can be considered the father of the chain-grate stoker. His two 1893 patents covered not only the design, but also the process of the forced draft and the zoning of the air in multiple air boxes.

1898—The Green Engineering Co. put the Green Chain Grate stoker on the market originally to burn the Illinois and Middle-West coals, but it is today also burning lignite coals successfully. The company has also developed a forced-draft chain grate.

1898-1904—During this period the Playford chain-grate stoker was brought out by the Rosedale Foundry & Machine Company.

1904-1906—Patents were taken out by the Babcock & Wilcox Co. on chain grates, and they put on the market a chain-grate stoker for use with their own boiler only. Their latest development is a forced-draft chain-grate stoker for general use.

1910—About this time the Westinghouse Electric & Manufacturing Co. brought out their chain-grate stoker.

1910—In this year The Illinois Stoker Co. first brought out the Illinois chain grate for natural draft, and later their forced-draft chain grate.

1911—Girtanner, of the Laclede-Christy Clay Products Co., filed applications for patents, which were subsequently granted, and this company is now manufacturing the Laclede-Christy chain grate.

1919—Harrington brought out his forced-draft stoker for burning anthracite, coke breeze, and Western coals, zoning his air in multiple air boxes.

1919—L. R. Stowe brought out a new type of stoker, consisting of alternating traveling grates and stationary tuyeres inclined toward the bridge-wall at an angle of 20 deg. This stoker is manufactured and marketed by the Laclede-Christy Clay Products Company.

Underfeed Single-Retort Stokers.

1838—Jukes patented a stoker in which the coal was thrown into the hopper and dropped down in front of the ram. By means of a hand screw the coal was fed in under the center of the grates beneath the burning fuel above it.

1844—Frisbie brought out and patented a stoker in which the fuel was fed from under the grates through a center opening.

1889—Evan William Jones invented and brought out the first underfeed stoker that proved successful, and he can be considered the originator of the underfeed principle, as he carried it forward to a success.

The paper mills in Oregon at that time were using green wood for fuel, difficult though it was to burn, owing to the moisture it contained. Jones, who at that time was president of the Union Iron Works at Portland, Oregon, was engaged to find some means to dry this fuel economically. The result of his study of the subject was a device for feeding sticks of green wood, in cordwood lengths, under a bed of burning fuel. The heat from the fire above dried the wood below, and as successive lengths of wood were fed under, the dry wood was advanced upward into the fire zone.

The success of this stoker led Jones to apply the same principle to burning coal. The grates were replaced by a retort, having dead plates on each side, from which ashes and refuse were cleaned. Tuyeres were placed along the edge of the retort, through which air was supplied to the fuel under pressure from a fan. This is the stoker manufactured by the Under-Feed Stoker Company.

1898—In this year W. R. Wood took out a patent on a stoker with a screw feed in place of the steam ram employed by Jones. This was known then as the American stoker. From 1901 to 1906 and 1907, Wood took out other patents on rocking bars in place of dead plates, and on side dumps. Later on he adopted the steam ram in place of the screw feed, and the final development of his original patents is the Type E stoker, manufactured by the Combustion Engineering Corporation.

1916—The Roach Stoker Co. entered the market with a patented stoker of similar design to the Type E, both of them using the steam cylinder for pushing in the fuel, as in the early Jones stokers.

1916—In this year the Moloch Stoker Co. brought out a device which was similar in design to the Standard Jones stoker, but instead of using dead plates, a clinker grinder was placed between the retorts.

1917—The Under-Feed Stoker Co. converted its standard stoker into a side-dump type, still maintaining the original principles of the former, however.

1917—The Detroit Stoker Co. brought out a stoker on the principle of the Jones, using a mechanical drive in place of the steam cylinder and substituting side dumps for the stationary dead plates.

Underfeed Multiple-Retort Stokers

1876—The Smith stoker was probably the first underfeed stoker to be used commercially and advertised. It, however, soon went out of use.

1903—E. E. Taylor, seeing the opportunity and the field for stokers of greater capacity, conceived the idea of the multiple-retort stoker. The first stokers of this type were manufactured by the American Windlass Co., of Providence, R. I., which company later reorganized under the name of the American Engineering Co.

Taylor's first patent was taken out late in 1904 and his stoker embodied the fundamental principle of a continuous fuel bed supported by legs of coal in multiple underfeed retorts. The patent claims also cover an inclined fuel bed, with the delivery of ash to the rear of the stoker, and the method of air distribution employed. Taylor was the first to use the crank drive.

1911—R. Sanford Riley made application for his patent, and subsequently started manufacturing and marketing the stoker that bears his name, the distinctive features being the moving sides of retorts and tuyeres.

1912—The multiple-retort stoker brought out by the Westinghouse Electric and Manufacturing Co. in this year was similar in design to the Taylor stoker, the difference being mainly in the angle of the ram, the bottom of the retorts, and the design of the tuyeres. Their stoker is driven mechanically.

1916—The Under-Feed Stoker Company brought out a multiple-retort steam-driven Jones A. C. stoker using the general design and principles of their standard single-retort stoker and avoiding all moving parts in the furnace.

1919—Detroit Stoker Company brought out a multiple-retort stoker in this year, which is similar inside the furnace to the Jones A-C, except that the retorts are laid flat instead of being at a slight angle; the rams, however, are driven by a specially designed mechanical drive instead of by a steam cylinder.

1919—The Frederick stoker is very similar in design to the Westinghouse, Taylor, and Riley stokers, and is now manufactured by the Combustion Engineering Corporation.

Underfeed Lateral-Retort Stokers

1918—H. E. Kleffel was granted a patent embodying the idea of a lateral retort.

1919—Blackburn and Armstrong stoker consists of a central retort placed longitudinally through the center of the furnace and feeding coal to lateral retorts branching out at right angles. The design is novel, and the stoker is manufactured by the Under-Feed Stoker Company.

Overfeed Inclined-Grate Stokers

1867—Vicars stoker is still manufactured in an improved form in England, but the points that are most interesting about it are that not only were inclined grates used, but the coal was fed by a plunger or ram, this being practically the first stoker in which that was done.

1878—Thomas Murphy brought out in this year his inclined-grate stoker of the inverted or V-shaped type. The grate bars have a reciprocating motion, and the ash is gradually worked down from the center of a clinker grinder. Mr. Murphy was undoubtedly the first to employ a clinker grinder with mechanical stokers, using in some cases one breaker and in others two breakers working together. These stokers are manufactured by the Murphy Iron Works, of Detroit, which is probably the oldest stoker concern in the country still manufacturing stokers having the same basic principle as those they first built.

1885—William R. Roney. Roney brought out the front inclined-grate stoker and was the first one to make a distinct success with this type in this country. It is manufactured and sold by the Westinghouse Electric & Manufacturing Company.

1890—Wilkinson Stoker is a front inclined stoker, but varies from some of the others in that steam jets are used to draw air through hollow grate bars. It was designed originally for burning small sizes of anthracite.

1897—Detroit Stoker Company took out patents on the Detroit V-type stoker, similar in design to the Murphy stoker, the clinker crusher being composed of rotating disk.

1904—The Wetzel stoker is a front-inclined overfeed stoker that operates on natural draft and has movable and stationary grate bars.

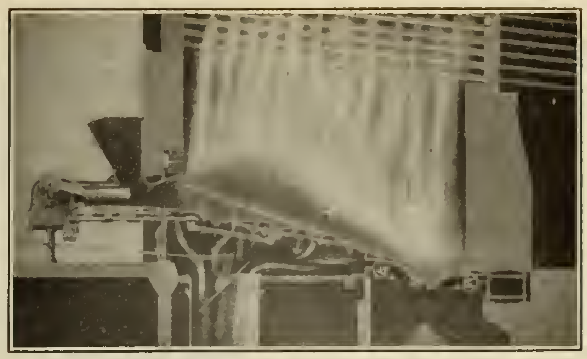
opment of the single-retort and consists of a number of single retorts placed close together and inclined with the ash discharge at the rear. As the coal is burned the ash is formed on top of the fuel bed and is floated to the rear and deposited on dump plates or into crusher pits from which it is readily removed. The continuous ash discharge consists of rotary toothed crushers placed at the rear of the stoker and set low so that a large, deep pit is formed for receiving the ash and burning out the last of the combustible material.

The secondary coal feed, that is, the feed from the retort to the fuel bed, is obtained in various ways. The Taylor stoker uses additional rams similar to the coal-feeding ram, which are placed in the bottom of the retort. The retort inclination is such that the rams are reciprocated horizontally. The Westinghouse and the Frederick stokers have a lesser inclination, and the secondary coal feeding is accomplished by large wedge-shaped castings placed at the bottom of the retort. These are reciprocated on an inclination corresponding to the slope of the bottom of the retort.

Have Similar Retorts

The Jones and Detroit stokers have similarly shaped retorts, and the secondary coal feed is obtained by small wedge-shaped pushers which are reciprocated horizontally in the bottom of the retort. The Riley stokers accomplish the secondary feeding by reciprocating the retort sides and the tuyeres. They also vary in the angle at which the tuyeres are placed—from horizontal in the case of the Detroit to 25 deg. in the Taylor stoker.

Tuyeres are placed between the retorts. and serve to convert the static head of air into velocity and direct the flow of air through the fuel bed. The tuyere designs naturally are different in each stoker.



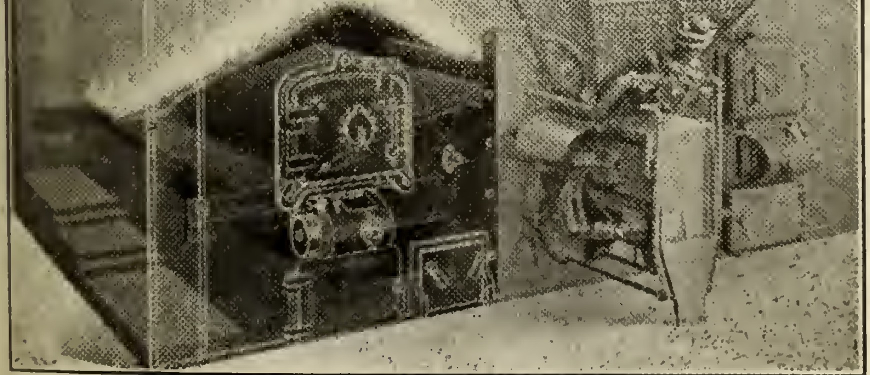
Multiple Retort Underfeed Type.

All designs are for forced draft and cannot be operated at any appreciable capacity with natural draft. The air for combustion is circulated beneath the furnace parts and thereby cools these parts before being discharged through the fuel bed.

In the operation of front and side-feed types of inclined overfeed stokers it is claimed that 150 per cent. of boiler rating can be obtained with 0.3 in. to 0.5 in. draft loss through the fuel bed, and that when forced draft is applied, it should be done with proper regard to air circulation and the maintenance of suction above the fire.

The operation of underfeed stokers is essentially as follows. The incandescent burning fuel is on top and is replenished throughout the entire retort length from beneath. As the coal emerges from the retort it is coked and spreads over the tuyeres, forming a homogeneous fuel bed across the entire furnace width. As the fuel approaches the surface the volatile matter is completely distilled off and the fuel completely coked. The surface consists of a layer of incandescent burning coke.

The air for combustion is introduced near the point where the fuel emerges from the retort. As the volatile gases are liberated they are thoroughly mixed with air. As the mixture passes up through the fuel bed, higher-temperature zones are reached and complete combusion of the volatile gases takes place when they pass through the white-hot coke at the surface.



Underfeed Single Retort Type of Stoker.

Smokeless Combustion

Smokeless combustion is obtained without the use of special mixing of ignition arches or special brickwork construction. As the fuel bed is replenished from beneath the surface, the burning incandescent coke which is on top is slowly moved toward the dump plates. As the ash is formed it is floated on the surface and is eventually deposited on the dump plates.

The control of the fuel bed is obtained by adjustments of the secondary coal-feeding arrangement. For good operation it is essential that the fuel bed be so controlled that the replenishing coal emerges from the retort through its entire length; the lesser amount being fed from the rear end of the retort.

With low-grade coals more fuel must be discharged from the rear end of the retort than with high-grade fuels. In general, the greater the quantity of ash in the coal, the longer should be the stroke of the secondary fuel-feeding mechanism.

With the underfeed stoker properly adjusted, fresh fuel will be fed up throughout the full length of the retort. Green fuel moving upward with respect to the tuyeres tends to keep them buried, and consequently the ironwork is in the comparatively cool zone of the fuel bed. For this reason maintenance is low on underfeed stokers.

Among prominent manufacturers of this type of stoker are: Underfeed Stoker Co. of Canada, "Jones Lateral Retort," "Jones A. C.," and "Sanford Riley," York Bldg., Toronto, Ont., Maclean Underfeed Stoker Co., "Maclean" 95-97 King St. W., Toronto; Taylor Stoker Co: "Taylor," 416 Philips Place, Montreal, Que.; Combustion Engineering Corporation, "Type E", "Type K" and "New Frederick" 1107 Bank of Hamilton Bldg., Toronto, Ont.; Detroit Stoker Co., "Detroit," 7340 Woodward Ave., Detroit, Mich., Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

Chain Grate Stoker Type

The chain grate type of stoker was first developed to burn high-volatile free-burning, high-ash, clinkering coals.

The development of this type has been gradual but definite, and has involved the successful burning of many coals having far different characteristics. All successes, however, have been dependent upon the application of the principles of progressive combustion.

Coal burning in any practical process involves some losses: a total conversion of the heat in coal into heat in steam is impossible. Costs of operation must also be considered. These facts determine that every combustion process must finally operate with a common-sense balance between the three important factors in steam-generation economy namely, maintenance, efficiency, and capacity.

Maintenance and Efficiency

Maintenance and reliability are closely related. The chain grate, with two-thirds of the grate surface out of the furnace and with a simple driving mechanism, was low in maintenance costs. In the earlier designs, however, some of the parts were exposed both to heat and wear. Parts necessarily exposed to wear or strain often did not have sufficient resistance.

The chain, which is the fuel-carrying part, is now subjected to but slight heating as a result of adequate ventilation. Stoker frames are not subject to wear and are not exposed to heat. When exposed to heat or wear, replaceable parts are provided.

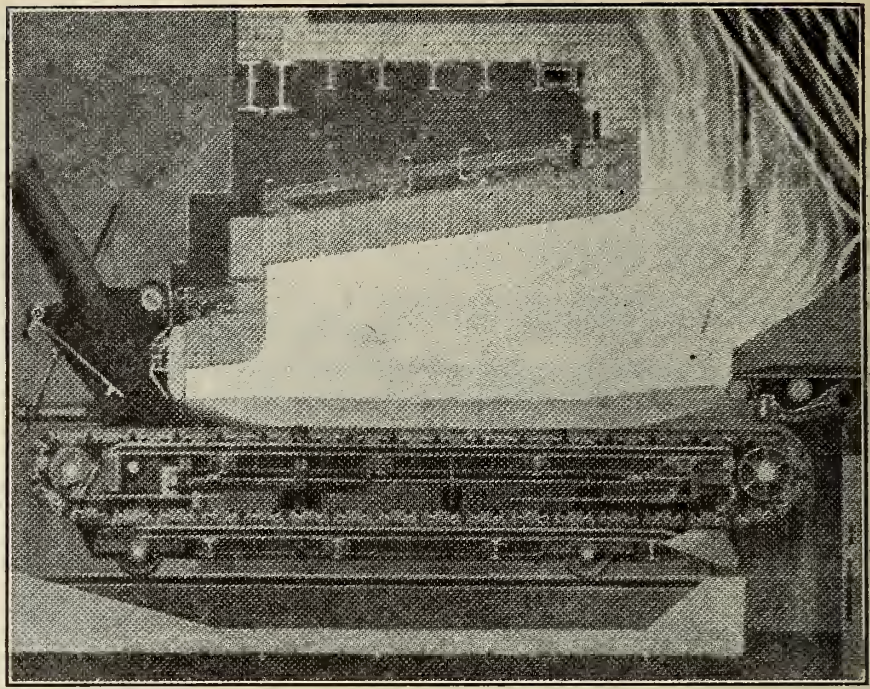
Improvements in Design

A grate surface moving through a furnace presents the problem of air seals along the sides of the stoker and at the rear. The reduction of air leakages at these places has contributed materially to modern economy.

Ledge plates or seals along the sides of the stoker have reached a high stage of development, resulting in the modern adjustable ledge plates for making a proper rubbing seal with the stoker chain, and including means for adjustment to keep this seal intact.

Meet Fuel Changes

The development in certain types of this stoker, of the ledge-plate flange adjustable against the side of the upper chain made it possible to raise and lower the stoker to vary the discharge opening under the water back in order to meet broad changes in fuel conditions. The improved results thus obtained indicated the desirability of a water back adjustable as to the height, and several designs were developed. These were for the most part difficult to construct or to maintain. From such designs the modern fuel retarder was developed. This is an adjustable member in connection with a fixed water back and bridge wall.



Another Type of Chain Grate Stoker.

The forced-blast chain-grate stoker is particularly adapted to the use of free-burning coals that require agitation of the fuel bed to break the crusting or caking action so often encountered with the slower-burning coking coals.

Obtain Good Results

With free-burning coals, which usually run high in sulphur and have ash with a low fusing point, results are being obtained, with uninterrupted operation, that equal the results obtained with other types of stokers using the low-volatile high-carbon coals.

With the underfeed type of stoker ability to control the draft over the fire is an important economical factor, obviating infiltration of cold air and maintaining good furnace temperatures. This in combination with the rate at which coal can be burned, ensures excellent efficiencies at maximum ratings. Latest designs allow of complete control over the width of the fire, which ensures a minimum of combustible in the refuse and the absence of sifting obviates waste.

Extreme width or depth of furnace are no impediments to modern underfeed design. Actual operations with all types of domestic and foreign coals has proven the success of this type of stoker.

Maintenance costs, with reasonable care in operation, should not, it is claimed, exceed 2c per ton of coal burned.

When burning buckwheat or coke breeze, fires 3 to 6 in. in thickness are carried on the grate and sufficient blast is carried in the first and second blast compartments to cause a gentle boiling or dancing of the fuel bed. Care must be taken, however, to regulate the thickness of fire and the blast so that excess carbon monoxide is not produced and continued combustion carried through the boiler to the chimney.

The forced-blast chain grate may be operated at continuous high overload capacities for days at a time with only slight variations in steam output of the boiler. This operation is made possible by the uniform thickness of the fuel bed, the uniform blast pressures carried, and the uninterrupted disposal of ash and refuse from the grate. A stoker, such as the "B & W" compartment type may be operated efficiently under natural draft when burning as little as 10 lb. per hour. Forced-draft combustion ratings reach 55 to 60 lb. of coal per sq. ft. of grate per hour.

Simple to Operate

Similarly to high duty underfeed stokers the forced-blast chain grate is simple to operate and flexible in handling varying load conditions. If properly handled it can be brought from banked fires to full load in time to meet any ordinary power-plant requirements. A cold boiler can be put on the line in 45 min. from the time of lighting the fires. The boilers can be operating at 150 per cent. of rating in 5 min. from the time it goes on the line, or it can be operating at 200 per cent. of rating in 7 min.

Automatic control has been successfully applied to both natural and forced-draft chain grates. With natural-draft chain grates the usual control is by means of a steam-pressure or steam-flow regulator controlling the boiler damper and the speed of the stoker engine or motor. With forced-draft chain grates several control systems are in successful service. The electrical control is applicable on motor-driven installations. The steam-flow regulator, controlling the air supply to the stoker and the speed of the grate, is giving successful results.

The steam-pressure regulator controlling the air supply to the stoker and speed of the grate is also giving excellent service. In case constant furnace draft is desired, the balanced control can also be applied, as in other types of stoker installations.

Natural vs. Forced Draft

Whether natural or forced-draft chain grates should be installed depends upon the conditions in the individual plant. The station load, banking periods, boiler absorption with or without economizers, as well as the limits of the draft available, are all involved.

Among prominent manufacturers of this type of stoker are: Babcock & Wilcox Co., "B. & W.", College St., St. Henry, Montreal, Que.; Illinois Stoker Co., Alton, Ill.; Combustion Engineering Corporation, "Coxe," 1107 Bank of Hamilton Bldg., Toronto; Green Engineering Co., East Chicago, Ind.; Laclede-Christy Company, St. Louis, Mo.

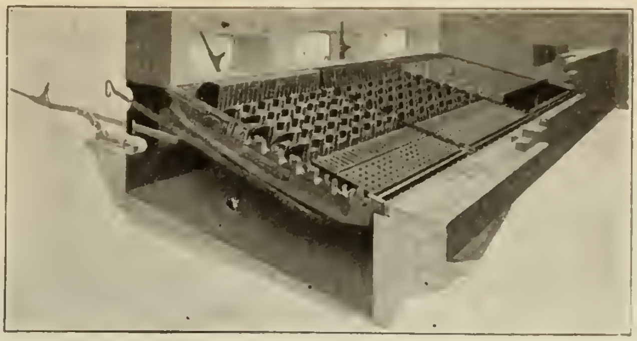
Semi-Automatic Types

The type of stoker that may be termed semi-automatic, in that it is intended for hand operation of the grates themselves, is designed to get away from the disadvantages attendant on hand firing and cleaning, and at the same time be adaptable for smaller units.

It is easily attached to any boiler, the only work to be done on the boiler fronts being the drilling of a few holes to support the lever brackets, which are set at the front of the boiler.

The grate is inclined to the back of the boiler, and the coal which is fed onto the front bars, is there coked, the volatile gases passing over the incandescent fuel bed, where final combustion takes place.

The coked coal is gradually worked down the inclined surface by the operation of the stoker bar handles, which are situated at the boiler front.



Hand Operated Stoker Type.

The operation of the handle turns the stoker's bars up into the fire about six inches, breaking up the clinkers and ash, and pushing it forward to the cleaning plate, while the coked fuel is also advanced along the inclined bars. There is thus a free passage for air through the fuel bed constantly maintained.

The cleaning plate at the lower end of the grate is counterbalanced, and a single pull on the lever is sufficient to dump the ash and clinker into the ashpit, without the loss of any unburned coal, and with absolutely no waste of time, therefore no drop in pressure.

Notable improvements have been made in chain grate stoker practice as regards air-tightness, cooling, size of combustion space, etc. A greater boiler capacity can be obtained by increasing grate size or by more intense natural or forced draft (0.50 to 0.60 in. for a combustion rate of 40 to 45 lb. per sq. ft. of grate per hour), but high and sudden overloads are best met by forced-draft chain grates burning 55 to 60 lb. of bituminous coal per sq. ft. per hour, with air at 2 in. pressure distributed through compartments between the runs of chain. It is claimed for such equipments that 200 per cent. of the rating can be reached in 10 min. from a short-banked fire, or in 52 min. from a cold grate.

Among prominent manufacturers of this type of equipment are: Waterous Engine Works, "Files," Brantford, Ont.; Engineering Machine Works of Canada, "National," St. Catharines, Ont.; McClave-Brooks Co., Scranton, Pa.; Combustion Engineering Corporation, 1107 Bank of Hamilton Bldg., Toronto; Cokal Stoker Corporation, "Cokal," 341 East Ohio St., Chicago, Ill.

Traveling Grate Stoker.

BELTING EFFICIENCY

Tests made of leather belting by the Leather Belting Exchange, Philadelphia, show that, with a reasonable shop tension, a transmission belt with its flesh side in contact with the pulleys will average only about 50 to 60 per cent. as much power as when the grain side is in touch with them.

On the other hand, at higher tension the flesh side will do much better, averaging from 50 to 100 per cent. more power than the grain side, the results depending, of course, on the belt and the conditions of service.

For the experiments, five 4-inch, 30-foot, single belts of different make, weighing from sixteen to eighteen ounces, were used. The conditions were standardized, and the belts were all thoroughly "run in" before the tests were made.

The following test, conducted at the same time, strikingly illustrates the low efficiency of a new belt. When first put on the pulley, the belt transmitted 12 H. P. at a slip of 1.2 per cent. After turning for five hours it transmitted 19 H. P. with the same percentage of slip; after thirteen hours it transmitted 24 H. P.; while after twenty hours it transmitted 31 H. P. with a slip of 1.6 per cent. According to the horse-power tables, its schedule transmission should have been 26 H. P.

To reverse the direction of rotation of a shunt motor, reverse the armature leads or shift the brushes backward past the polepieces an amount equal to that which they were originally forward of the polepieces; where the winding is such that the neutral brush position is opposite a pole piece, the brushes will be shifted backward a distance equal to the pole pitch plus twice the lead.

Lubrication by forced circulation is the best method known, where the oil is delivered into the bearings under pressure in a copious stream, collected and returned after being filtered and cooled. Pressure and large passages insure an ample supply, and the comparatively cool oil conveys heat from the bearing in proportion to its weight, specific heat and temperature rise.

Service Engineering at the Mount Royal Hotel

One Third of Total Cost or Approximately $2,000,000 Expended on Service Engineering Features of "The House of Ten Thousand Lights"

*BY WALTER J. ARMSTRONG

THE Mount Royal Hotel, including permanent equipment, cost in the neighbourhood of $6,000,000.00 of which, approximately one-third, or $2,000,000.00 was expended on service engineering features. The building has a content of 9,363,000 cu. ft., with a total floor area of 766,000 sq. ft. or approximately 18 acres on fourteen floors. This includes basements and part of mezzanine floors. There are 2,500 rooms in the building, both small and large.

Of these 2,500 rooms approximately 2,300 had to be heated, and this required 60,000 sq. ft. of direct radiation, divided into over 2,500 separate units. The direct heating of the larger spaces is supplemented with indirect heating or supply ventilation, and approximately 12,000 sq. ft. of indirect radiation is provided for heating the air for these purposes. The temperature of the more important rooms and of air for ventilation is automatically controlled.

Steam is used for heating the building, heating air for ventilation, and heating water for all purposes, also for cooking and warming in the various kitchens, and for drying and ironing in the laundry. Piping used for these purposes, together with that required in the boiler and engine rooms, is over 20 miles in length, varying in sizes from ½ in. to 20 in. in diameter, and having a total weight of approximately 150 tons.

10 Separate Systems

There are 10 separate supply ventilation or indirect heating systems, supplying 200,000 cu. ft. of air per minute—and 15 separate exhaust ventilating systems, exhausting 300,000 cu. ft. of air per minute—all of the mechanical type, utilizing 25 motor driven fans. The reason for providing so many separate systems was partly due to the large area of the building, and partly due to the fact that many of the rooms are not in use continuously or simultaneously.

The air in the various rooms is changed from 4 to 20 times per hour, the amounts supplied or exhausted being fixed so that the flow of air is into rooms where odors are likely to occur. Air supply is taken from the top of the building to ensure maximum purity, and in the case of the more important systems the air is washed and humidified, and during certain portions of the year also cooled. This air is distributed through sheet metal ducts, having a total weight of 200 tons.

Walter J. Armstrong

Engineer in charge of design and installation, Ross & MacDonald.

In connection with the plumbing, two problems appeared to be of more importance than the others. These were:—

1st. To ensure the continuity of water supply.

2nd. The solution of the drainage problem.

Own Water Supply

The Water Works Department finally agreed to permit connection with their 140 lbs. pressure main on Peel Street and their 40 lbs. pressure main on Burnside Place, but we were not satisfied with these alone, due to failure of water supply in Montreal in the past, and we therefore felt that the hotel should have a water supply of its own—and thus a 10 in. diameter well was sunk to a depth of 900 feet, and from tests made at this depth a supply of approximately 7 000 gallons per hour of an excellent quality water was obtained.

This not only practically assures water supply at all times but also showed a very handsome return on the expenditure. This water is pumped into a tank on the mezzanine floor by means of compressed air, from which it is drawn for cooling purposes in connection with the refrigeration plant, after which it is pumped into two 20,000 gallon storage tanks at the top of the building, and again used through the various plumbing fixtures.

As the elevation of the city sewer is only a little below the elevation of the basement floor, it was impossible to place a drain under this floor connecting with the sewer and obtain the usual slope asked for by the city, and it would have been disastrous to connect fixtures and apparatus in the basement direct to such a drain. It was also impossible to raise the building out of the ground 1 in. on account of the 130 foot city by-law, neither was there sufficient room on the basement ceiling for so many and large branches of the drainage system. We were finally permitted by the various parties interested, reluctantly by some, to place the main drain under the basement floor, provided no fixtures or apparatus on this floor were directly connected to it. Separate and independent drainage systems were provided connecting to three electric driven duplex ejectors, which pump all basement drainage into the main drain.

Water Softening Plant

The water consumption was estimated to be 350,000 gallons per day, with a maximum demand of 60,000 gallons per hour, while the hot water maximum demand was estimated at 20,000 gallons per hour. Records taken by the operating company show that these quantities are approximately correct. All of this water before being used is filtered. In addition to this, a plant is provided for softening water for particular uses.

135 hose lines are installed for fire protection purposes, in addition to which in workshops, storerooms, and similar places, automatic sprinklers are provided. Piping in connection with the plumbing and allied systems is over 30 miles in length, varying in sizes from ½ in. to 20 in. diameter, and having a total weight of about 500 tons, made up of cast iron, wrought iron and brass piping. The latter, that is the brass piping, which was used throughout for hot and drinking water lines, weighs about 40 tons. There are 3,320 plumbing fixtures, exclusive of those in kitchens and laundries, and 9,700 bathroom accessories.

The controlling factor in arriving at the passenger elevator requirements was the carrying of passengers between the lobby floor and the ball and banquet rooms located at the top of the building. At a most conservative estimate, the six passenger elevators provided in the central group will carry 1.000 persons one way between these two terminals in twenty minutes—or if only four of these elevators are utilized for this purpose, they will handle the same number of passenger in 30 minutes.

The next most exacting elevator demand is that for room service and three

---

Sectional view of stoker showing series of coal feeding plungers.

(3) elevators have been provided for this purpose alone.

Total of 16 Elevators

There is a total of 16 elevators and dumbwaiters in the building, all of which are equipped with the latest type of safety devices, and all passenger elevators with threshold illuminators, flashlight signal systems, and indicators. An indicator is also provided on the lobby floor, which shows the elevator starter the promptness or otherwise with which calls on the various floors are answered.

If I were asked to suggest a name for this, the largest hotel in the British Empire, I would immediately reply, "The House of Ten Thousand Lights." As a matter of fact, there are over 10 000 lighting outlet boxes, having connected thereto approximately 15 000 lamps.

In addition to the lighting, the electrical work includes:—

Wiring for 150 motors, ranging in sizes from one-eighth to sixty horsepower; wiring system for electrical cooking and baking having a connected load of 200 h.p.; signal systems of various types to speed up the service for the convenience of guests, such as carriage calls; electric time clocks and time stamps, also fire alarm system.

70 miles of conduits, ranging in sizes from ½ in. to 4 in. in diameter, are provided for electric wires. The wires have a total length of over 300 miles, which is approximately the distance between Montreal and Toronto.

Over 1 200 Telephones

As there are over 1 200 telephones, no small portion of these amounts of conduits and wires was provided for talking purposes. I suppose if President Frank was asked to suggest a name, he would call it—"The House of One Thousand Voices."

To me, the most interesting part of the electrical work is the provision made for continuity of service. Electrical energy for all purposes may either be generated by the building plant, or purchased from a local power company, and the main switchboard is so arranged that any portion desired of the electrical load may at any time, be either taken from the Power Company's lines or from the Building Generating Plant. By this arrangement it is possible at all times of the year to make the amount of exhaust steam available just equal to the amount required for heating purposes. Provision is also made for an emergency service from the Power Company.

If electrical energy should fail at any time, many parts of the building would be in total darkness; the elevators would cease to operate, as would all electrically operated apparatus, such as pumps and equipment in the kitchens and laundries. Thus you can readily realize how serious even a short interruption would be. With the equipment provided any interruption is a remote possibility.

If a hotel manager were asked, "What is the largest problem in hotel management?' I have no doubt he would say—"The satisfactory feeding of the guests." In the Mount Royal no effort has been spared to simplify this problem. Five separate kitchens have been provided four of which are more or less auxiliary to the main kitchen. Some idea of the problems may be realized from the fact that equipment is provided to serve from day to day, without confusion or unusual effort from 6 000 to 7,000 meals, and many more from time to time, as the occasion demands. This figure does not include afternoon teas.

In the employees' cafeteria, equipment is furnished to serve 1,200 meals per day. Approximately 400 separate pieces of permanent kitchen and service equipment are installed. This includes equipment for all bread, pastry, ice cream and candy making, as well as that for the usual cooking and serving, and practically each piece requires either water, waste, steam, gas, electrical or brine connection and many pieces require a number of such connections.

Only so-called "raw foods" are purchased. Large storage rooms and refrigerators are provided and maintained at the proper temperatures by mechanical refrigeration to preserve large stock of raw foods, and numerous smaller refrigerators for "ready to cook" or "ready to serve" foods.

At one time during construction it was practically decided to omit, at least for the time being, the laundry, but after considerable investigation it was learned that no laundry company in Montreal, in fact, if my memory serves, no two companies, were in a position to handle the linen from the hotel. The equipment as provided is of ample capacity not only to handle the hotel laundry, but also for handling linen, and so forth, for guests. This laundry has a capacity of from 7 to 10 tons, or 18,000 pieces per eight hour day; the 18,000 pieces include the average run of hotel and guests' linen. Equipment such as washers, extractors, tumblers, flat work, ironers and the like, are individually motor driven and in the case of washers, extractors and tumblers, are automatically controlled.

A smaller laundry for the use of the maids is provided on the top floor.

Refrigeration Needs

Although modern heating, ventilating and plumbing systems, electricity and elevators, make a hotel like the Mount Royal possible, the present day refrigeration plant contributes in no small way to the enjoyment and health of the guests and to economy in service. The duty of the plant in the Mount Royal is to maintain in 94 separate refrigerators temperatures varying from 10 deg. to 45 deg. Fahr., to make 30 gallons of frozen desserts per hour, to manufacture 10 tons of ice per day, and to cool 450 gallons of water per hour for drinking purposes. Brine at approximately 0 deg. Fahr., is used for freezing ices and for cooling refrigerators in which are stored foods which must be frozen and kept frozen. Brine at from 10 deg. to 15 deg. Fahr. is circulated through all other refrigerators. There are two (2) ice freezing tanks containing a total of 240 100-lb cans. This size of can being selected for ease in handling.

A separate small autematic plant is provided for cooling refrigerators in the banquet room kitchen located on the top floor.

In this day of high priced labor it has been found that it is more economical as well as being more positive and reducing delays to a minimum to send messages, complaints, orders, bills, and even small parcels such as keys, through pneumatic tubes rather than by messengers. Thus an extensive system has been installed connecting the various operating departments. Tubes are also provided between restaurant cashiers and the front office. If a guest of the house after charging his dinner to his house account rushes from the restaurant to catch a train, paying his bill on the way, he will find that the front office has a record of the meal only finished a few minutes before.

Scales are provided so that every pound of supplies received, whether they be coal (which is purchased by the ton), or food supplies (which are purchased by the pound), may be weighed before being received.

Shops for repairing furniture, linen and silver, as well as all sorts of mechanical and electrical apparatus, are equipped with modern power driven labor saving devices.

Electrically driven printing machines also form a part of the necessary equipment.

Efficiency at Maximum

Although architects and owners do not always see such matters from this point of view, nevertheless it pleases me to think of the boiler and engine room equipment as being the heart, and the pipes, wires, etc., emanating therefrom as being the arteries and veins of the building, and only as these essentials of the building's anatomy are healthy, efficient and lasting, so may the goal for which the project was promoted be fully realized.

Space do not permit saying very much concerning the boiler and engine room equipment. I do wish to state, however, that in selecting the boilers and stokers, the coal and ash handling equipment, engines, generators, pumps, and the like, the effort was made to obtain a plant of maximum lasting qualities and efficiency in operation, interest and maintenance charges, together with available space conditions being taken into consideration. Tests of the boiler plant made to date show a steam generation of 10 lbs. per 1 lb. of coal, which fulfills the efficiency endeavor.

As much as possible of the equipment is made automatic, and by this I mean stokers, draught fans, damper regulators, feed pumps, etc., respond automatically to the load demand. In this way the plant is operating a maximum efficiency for any condition of load. Efficiency instruments, meters and gauges are supplied, so that the operators may quickly tell whether the automatic features are responding to variations in loads as they should, and in the case of the boilers, the work done by any one may easily be compared with that of the others. Quantities of hot and cold water, steam and electric current used in the various departments are recorded daily. The heat remaining in the steam after passing through engines and pumps is utilized for heating the building, air for ventilation or water for various purposes, and the condensation from such systems is again returned to the boilers; thus practically all of the heat of the steam is utilized.

The elimination of noise and vibration caused by engines and compressors has always been a difficult problem in hotels. Thus it may be of interest to you to know that the foundations for engines and compressors in the Mount Royal Hotel are carried down to solid rock over 20 feet below the level of the engine room floor the foundations are encased with cork. These precautions may at first thought seem unnecessarily elaborate, but the satisfactory results obtained appear to justify the expenditure.

Personals

Cama, Norton & Co., 11 Elphinstone Circle, Bombay, India, would appreciate receiving catalogues from Canadian firms exporting electrical machinery, devices and appliances for plants.

Dunn's Leather Packings, Ltd., is another new industry for Hamliton, Ont. The company has recently been incorporated with a capital of $40,000, to manufacture washers, packings, valve leathers, and leather specialties. J. M. Dunn is the manager.

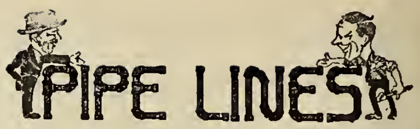
Disher Steel Construction Co., 95 King Street East, Toronto, have been incorporated with a capital of $500,000. C. E. Disher is the president of the new concern, and was formerly junior partner of the firm Hepburn & Disher, Ltd., 71 Van Horne Street.

E. L. Cousens, consulting engineer of the Toronto Harbor Commission, has been appointed one of the consulting engineers for the Port of New York, in addition to his present duties in Toronto. Mr. Cousens is one of twenty such engineers appointed. The cost of the complete New York project will total between $50,000,000 and $75,000,000.

J. Amos Johnston has been appointed sales manager in the Ottawa district, for the Eugene F. Phillips Electrical Works, Ltd., Brockville, Ont. Mr. Johnston was formerly manager of the Public Utilities Commission for the city, and prior to that district inspector for the Hydro-Electric Power Commission of Ontario.

Eric D. Todd, the newly-appointed municipal engineer of South Vancouver. B. C., who assumed his duties April 1, was employed as engineer in charge of road construction and maintenance in the electoral districts of South Vancouver, North Vancouver, Richmond and Dewdney by the provincial government since 1917.

Born in Edinburgh, Scotland, Mr. Todd received his technical education at the Lewis institute of Technology, Chicago, Ill.



UNCOVERED IN ANY OLD SPOT

In condensing it is usual to use about 28 times as much injection water as the steam to be condensed; the temperature of the hot water should not be above 120 degrees.

* * *

They say a man always finds that which he earnestly and persistently seeks. Then look for 80 per cent. efficiency in your boiler plant.

* * *

If it is suspected that an engine piston is leaking steam, place the engine on the crank-end dead center, and after removing the cylinder head, on the head end, admit steam back of the piston. Any leak can be readily detected.

* * *

A modern boiler room is a brain proposition, not a muscle job. You've got to double your brain power, Mr. Engineer, to stay in this man's game.

* * *

After removing loose dirt with a stiff brush, files can be cleaned of grease by boiling them for about 40 minutes in a solution of ¼ lb. of saleratus to a quart of water. The files should then be thoroughly washed in clean water and after being dried should be submerged in a solution of ¼ lb. of sulphuric acid to a quart of water. After remaining in this solution for about 12 hours, should again be thoroughly washed, quickly dried and given a light coating of kerosene to prevent rusting.

* * *

A boiler flue is so named because it is the place where the gases fly faster when the temperature soars.

* * *

End play of a crankshaft may be caused by the crankpin brasses being out of line and bearing alternately on opposite ends of the crankpin, or to the shaft being out of line, causing a wobbling motion of the flywheel or, in a single crank engine, by lost motion in the crankshaft bearings.

* * *

It's better to wear a boiler tube out with a tube cleaner than to have it burn out from scale.

* * *

Surface condensers are allowed from 1½ to 2½ sq. ft. of tube surface per indicated horsepower, or better, 1 sq. ft. of tube surface for every 8 to 12 lbs. of steam to be condensed per hour.

* * *

There's a thimble full of air in every quart of make-up water. If you don't get it out, the oxygen will most surely pit your boiler.

* * *

Failure of a direct current generator to build up its voltage may be the result of lost residual magnetism, an open field circuit, reversed field connections, wrong brush position, poor brush contact or a short circuit.

Editorial Comment

CAMPBELL BRADSHAW, Editor

Time for Study

IN THE average power plant the more simple the equipment can be made, the greater the opportunity for the engineer to maintain it in an efficient condition.

When the firing is performed by automatic stokers and the draft regulated automatically, there is a far greater likelihood of the operating force maintaining the best conditions, than in a plant where this work is done by hand.

The investment must be considered from several angles. There are tangible returns annually from the elimination of labor; the economy possible from the use of a lower grade of fuel; and the saving due to better combustion and general efficiency which sometimes alone offsets the initial cost by the possibility of installing a smaller boiler plant, due, of course, to the mechanical stoker being capable of carrying heavy over-ratings for short periods.

Indeed even in the small plant considerable fuel economy can often be effected by the installation of one of the many hand operated stokers or dumping or moving grates.

Such an investment pays further dividends in the shape of a more contented fireman and a better kept boiler room, for it must be remembered that men forced to undergo physical fatigue to keep up steam cannot be expected to give their undivided attention to efficient operation.

Their chief interest naturally centers in maintaining the required pressure with the minimum of exertion.

When operations are practically automatic, the same load cannot only be carried with less than one third of the boiler capacity with labor at a minimum but the functions of the operating force have become more mental than physical.

This satisfactory result merits more attention in Canada than is generally given it, for if engineers and firemen are expected to give careful study to efficient operation they must have time for such study without encroaching on the hours necessary for their other duties.

And so it is important to remember that the automatic regulation of the boiler room so as to promote the highest degree of mental vigor is a very real factor in efficiency and economy.

Brains at a Discount

BRAINS that are merely cultivated, or cultured as brains, are at a decided discount in the world's markets.

Brains, highly disciplined to serious thought, manicured and polished, shine in obscurity. There is no demand for them unless of the rank of genius.

A writer in a current magazine expresses it this way:

"When educated men were scarce, disciplined brains could be sold at a good price on a virgin market. Then the news went out that higher education meant good pay and the past three decades have so glutted the market with disciplined brains, that we are now confronted with the incongruity of an engineer in greasy overalls rightly commanding better pay than a professor in white collar, whose learning involved an outlay of $5,000."

Yes, fortunately, to-day the demand is for workers with brains trained to act through the senses. The psychological vocations find a market only when specialized and then they are graded until only the very best of them can compete with the "engineer in greasy overalls."

The concert pianist, the violin virtuoso, the lawyer, physician, or teacher who found economic comfort three decades ago in the broader field, has now been relegated in Canada to the rural community for even a local fame.

But the man whose trained brain was trained by experience, and if also in a university so much the better, to find expression through the senses, has come into his own.

The academics of a former generation are the high school graduates of this. The statesmen of a former century would be the demagogues of to-day, save for the geniuses.

A precarious existence is the reward of mere brain culture, which is now classed only with the impracticables. But skill such as that expressed in the production of power, fortunately rules the world.

* * * *

Blind Prejudice

PREJUDICE—a judgment or opinion formed hastily without due examination of the facts or reasons essential to an impartial consideration of the value of the power plant equipment in question.

It is unfortunate that once in a while we run across a man who is sadly afflicted with one or more prejudice—unfortunate because there are so many real opportunities going to waste for want of the man who will accept the word and experience of his successful fellow.

The engineer who not so long ago ordered a stoker installation "thrown out" of his boiler room although the identical equipment was installed in a similar plant a few weeks later and has since given perfect satisfaction, wouldn't think of wearing eyeglasses that blurred his vision any more than he would tie a ball to his feet when he was going to run a foot-race—yet day by day he continues to grope about blindly in a dark abyss of prejudice wondering why he doesn't get anywhere.

Write Your Editor

SHARING of knowledge so that it may be applied whenever wanted, is characteristic of human progress and typical of engineering co-operation. Everyone of us should be interested in engineers who are doing things, for to read about what they are doing helps us to do better what we are doing.

The man who works out a new idea, puts that idea into practice and then tells the results so that they can be passed along to readers of Power House helps himself and helps his fellows. Everybody to-day is interested in just one thing—success. The story of your success helps the other fellow and the other fellow's story helps you.

While it is not always easy to send in ideas that are of wide interest, the present tendency in the engineering world is to co-operate freely in supplying information—so take a hand, get the writing habit and tell the go-between—your editor—what you are doing and how you are doing it for when you help Power House to help power plant efficiency, you are really helping it to help you.

Power Plant Economy Paramount in Britain

E. R. Hanson Declares Fuel Costs Have Trebled Since Pre-war Days, Forcing Engineers to Seek New Methods of Cutting Costs of Power Production

By KENNETH MacTAGGART

WHILE much is being written of the necessity of power plant economies in fuel and methods of operation in Canada to-day, the demand for efficiency in coal burning is nowhere more insistent at the present time than in Great Britain where coal has soared to three times the pre-war price.

This was the outstanding feature of conditions observed by E. R. Hanson, secretary-treasurer of Mutual Coal Mines of Canada, during an eight weeks' trip abroad.

Factories utilizing steam for power purposes in the British Isles are entirely dependent upon coal because of the lack of oil or other substitutes used on this side of the Atlantic, Mr. Hanson declares. Pulverized fuel is practically an unknown quantity.

Only Fire In Forge

This condition has resulted in a great increase in the use of electricity. In one large mine visited in the Glasgow district the boiler room has been superseded by a large transformer and the engine room housed electric motors. The only fire to be seen on the property being in the blacksmith's forge.

So great is the demand for coal that urgent steps are being taken to reclaim the mines flooded in the Glasgow district by striking miners and several new pits have been sunk lately equipped with the most modern types of mining machinery.

This unprecedented demand for fuel has in part been caused by the action of France in the Ruhr district causing utter stagnation in coal production there, a condition which has taxed the available supply of substantially the only raw product that Britain produces for export.

Cut Cost of Power

Manufacturers are greatly embarrassed by this drain on the nation's natural resources and every means is being taken to reduce overhead in the production of power.

This "famine," coupled with the fact that industrial progress in Britain is at a standstill as far as quantity production is concerned, has so greatly increased the cost of operation that large numbers of firms have found it necessary to close their plants, forcing thousands of men out of work.

On the Clyde, shipbuilding has been so greatly hit by this industrial depression that there is absolutely no demand for labor. The majority of the mechanics have been without work for months and the few who are working are receiving the meagre wages of the common laborer in many cases.

Despite this inactivity, the evidences of poverty which one would naturally expect to see on every hand are lacking. In fact, the condition of the working man and his family are far advanced as compared with twelve years ago when Mr. Hanson last visited the Old Country.

Men are better dressed to-day; children are receiving a better education and all in all it would appear that living conditions have risen to a much higher standard in the last decade.

The paradox this surface "prosperity" implies is, however, directly attributable to the system of "doles," as it is called, on which, unfortunately, so many families are dependent. This method of granting relief to persons unable to obtain employment has been the target of the press and the political opponents of the government alike on the ground that it tends to encourage laziness by officially sanctioning "loafing."

Whether you are operating a boiler plant or running a bank, it is up to you to decide whether the crowd shall come to you under the "big top" or in the side show. The answer is the degree of concentration plus enthusiasm that you put into what you are doing. Even if you don't like to hand fire a boiler, do it for all you are worth. Make every shovelful contribute something to your experience, something to your ability, but close the switches to the spur lines and keep on the main track.

On the contrary, however, the men are eager to return to work, accepting positions in many cases which pay less than the amount they had been receiving in "doles."

When the condition of the industrial world in Europe is taken into consideration, it is self-evident that these inequalities must temporarily exist although there can be no doubt of the fact that they will right themselves at an early date.

Seek Better Jobs

In the meantime, however, until the wheels of industry have regained their former impetus, the average workman must obtain a better means of deriving a livelihood, and to do this without delay he is reviewing other spheres for his activities in which the prospects of employment seem to warrant emigration.

Mr. Hanson believes that such families should be encouraged to come to the Dominion as they would provide the best type of population obtainable to develop the agricultural resources of the country.

Large English landowners are finding themselves in such a position, due to the heavy taxes which the government has found it necessary to levy, that they are being forced to liquidate their holdings. This is producing a large amount of liquid capital which, because of the possessors' reluctance or inability to reinvest in Britain, must ultimately find its way abroad, preferably the colonies.

Cites Canada's Wealth

Where in the world to-day, Mr. Hanson asks, can this money be put to better use than in Canada with its unlimited farming tracts, its undeveloped mining resources and the many manufacturing industries which offer innumerable opportunities for safe investment.

Whatever the final outcome may be, however, the large industrials are in a very optimistic frame of mind, viewing the situation with anything but alarm and daily observing a gradual upward trend in the business world.

The owner of one of the largest coast trading and shipping firms declared, the day Mr. Hanson sailed on his return trip, that business prospects were brightening on every hand. Such expressions reflect the cheery belief expressed by everyone in Britain's infallible ability to overcome all obstacles in her triumphant return to leadership in the industrial circles of the world.

Book Reviews

Steam Power. By C. F. Hirshfeld and T. C. Ulbricht. Second edition. John Wiley & Sons, New York; Capman & Hall, London. Cloth, 5 x 8 in., 174 pp., illus., diagrams, $3.25.

In preparing this textbook the authors have attempted to collect in a comparatively small book such parts of the field of steam power as should be familiar to engineers whose work does not require that they be conversant with the more complicated thermodynamic principles considered in advanced treatises.

They have therefore eliminated mathematical treatment as far as possible and confined themselves to giving a correct viewpoint with regard to the use of heat in the power plant, to supplying what is required to solve common power-plant problems and to describing the more common types of apparatus.

Cutting Steam Costs in Hand Fired Boiler Plants

30 Per Cent. Saving in Fuel Costs Effected by a Few Simple Changes in the Furnaces and in the Control of the Operation of the Boilers

* BY A. R. MUMFORD

DURING the course of the investigation of a hand-fired return-tubular boiler plant, it was found hat the average cost of fuel to produce ,000 lb. of steam was $0.5287. Tests onducted after some simple changes had een made in the furnaces, and in the ontrol of the boilers, showed the preious high cost of fuel per 1,000 lb. of team could be reduced to the reasonable igure of $0.3540, or the equivalent of ver 30 per cent. saving in fuel cost.

The boilers were the ordinary returnubular type, 18 feet long and 56 inches n diameter, set 27 inches above grates, feet deep and 5 feet wide. The bridgeall rose to within 5 inches of the shell f the boiler. The space behind the ridgewall had been filled in so that the loor of this space was only 20 inches elow the shell of the boiler.

This form of setting is believed to be ommon, and results in smoky and inomplete combustion when bituminous al is used for fuel.

Combustion Space Small

The combustion space, in the original nstallation, was small, and the gases ere exposed to the cooling action of he boiler during all of their passage hrough the setting, and, what is peraps more important, were not subjectd to any thorough mixing action. These onditions made it possible to burn tuminous coal without producing more moke than was permitted under the local egulations governing the emission of moke. For this reason, pea-size anthraite was burned during the greater part f the day, and the plant was able to ırn bituminous coal only at night when he demand for steam was somewhat ss than during the day and when the moke could not be seen.

The presence of black smoke in the ases issuing from a stack indicates hat the gaseous products formed durg the combustion of the coal are not ompletely burned. In order to burn ases completely it is necessary to mix hem with a certain proportion of air hile the gases are so hot that the reulting mixture will be above its igniion temperature.

There are limits to the amount of air hat can be mixed with a certain amount f any combustible gas to form an inlammable mixture, and increasing or ecreasing the amount of air above or elow these limits renders the mixture on-inflammable, so that it may be imossible to ignite it.

The rate of combustion of the inflamable mixture will vary with the proportions of gas and air, it is desirable to mix the gases rapidly with air in such proportions that they may burn quickly in the furnace and combustion chamber. Thus the problem to be solved, before the use of anthracite could be discontinued and bituminous coal used at all times without violating the regulations governing the emission of smoke, was to completely burn the gases formed during the combustion of bituminous coal before they left the setting.

Mixing Device Missing

The principal difficulties presented by the original setting were the small volume of the combustion chamber, which shortened the time allowed for the combustion of the gases; and the absence of any mixing device in the path of the gases which would have caused mixing of the combustible gases and air by changing the direction of flow of the gas stream and by changing its velocity at some point or points in its path.

The first obstacle to overcome was the small volume allowed for the combustion of the gases. On account of mechanical difficulties involving excessive cost, it was not feasible to alter the relative position of the grates. The combustion chamber beyond the bridgewall, however, had been built up from a concrete floor with filling and a layer of loosely-laid brick, and by removing this filling the distance of the floor from the shell of the boiler was increased from 20 to 30 inches.

It does not make a bit of difference whether you are an engineer or diplomat, there are times when the full power of your understanding will be called into play, times when no matter how fair you try to be, you will be thought unfair. How well you are able to work out that kind of a situation will reflect just how good a general you are at heart. The degree to which your own men understand you, will determine just how loyal they will be to the things for which you stand.

This increase in combustion-chamber volume permitted the gases to move at a slower speed for a given rate of combustion and excess of air, and therefore allowed them more time to burn completely. The second obstacle presented to complete combustion was the absence of any mixing device in the path of the gases. This was easily overcome by the installation of two semi-obstructing arches, one over the bridgewall and one in the combustion chamber. The vertical distance between the shell of the boiler and the top of the bridgewall was only 5 inches in the original installation, and this distance had to be increased to 10 inches before an arch could be placed over the bridgewall. This arch over the bridgewall closed off the former opening around the shell of the boiler, and reduced the area available for gas passage from 5.6 square feet to 1.7 square feet.

Arch Was Extended

The arch was extended for three feet from the front edge of the bridgewall in the direction of gas flow, to provide hot fire-brick surface for the ignition of any combustible gas-air mixture not previously ignited. The reduction in area caused a temporary increase in velocity, which resulted in a turbulent flow, so that mixing was greatly assisted. The increase in velocity and the mixing action were accomplished at the expense of the available draft, and this is the determining factor that governs the extent to which such obstructions may be employed.

Just beyond the bridgewall the area available for gas passage is 12 square feet, an increase of 10.3 square feet over that available above the bridgewall.

This increase in area considerably reduces the velocity of the mixture of gases which have come through the restricted area and so gives them a longer time to burn. The deflection arch in the combustion chamber was of single-span construction, extending from the floor to the boiler, and leaving only a semi-circular opening 4.15 square feet in area next to the floor of the combustion chamber.

This deflection arch caused the gas stream to turn towards the floor of the combustion chamber, and further assisted in mixing by causing a second contraction, increase in velocity, and expansion of the gas stream. These changes in furnace arrangement in connection with the introduction of an improved method of firing permitted the substitution of bituminous coal for anthracite at a reduction of approximately $3.00 per ton in delivered price.

Found Firing Irregular

It was found during the course of tests, made before the furnaces and method of firing were modified, that the operation of the boilers was left entirely to the firemen, as long as steam pressure was maintained above 100 pounds and below the blowing off point of approximately 110 pounds. This method resulted in irregular firing and increased fuel losses because the firemen added fuel or worked the fires only when the steam pressure was decreasing. The dampers on all of the boilers under fire were always wide open, and if the steam pressure rose toward the blow-off point the firemen reduced the rate of combustion by closing the ash-pit doors, and if the steam pressure continued to rise the rate of combustion was further reduced by opening the fire doors.

---

*Assistant fuel engineer, Bureau of Mines.

Closing the ash-pit doors to reduce the rate of combustion has long been recognized as very poor practice, and results in overheated grate bars, increased clinker formation, and increased flue gas losses.

Opening the fire doors to reduce further the rate of combustion, not only results in the same evils that result from the closing of the ash-pit doors, but in addition cools the boiler unequally and puts a local stress on the boiler which, especially with fire-tube boilers, increases the wear and repairs necessary on boiler and brick work. The use of this method of controlling the rate of combustion is brought about by irregular intervals between firings, varying quantities fired at each firing, and inaccessible dampers.

Open Ash-pit Doors

The evils resulting from the closing of the ash-pit doors are caused by the increase in the draft throughout the boiler. When the ash-pit doors are open the draft available at the damper of each boiler is used to draw air into the ash-pit and through the grates and fuel bed, thereby burning the coal; to move the products of combustion through the boilers; and to draw air into the setting through any openings in the fire doors or cracks in the brickwork or boiler casing.

This influx of air through cracks in the brickwork or boiler casing is objectionable, and should be prevented by keeping the brickwork and casing air tight. When the ash-pit doors are closed the amount of air entering under the grates is greatly decreased, thereby decreasing the rate of combustion and the quantity of the products of combustion flowing through the boiler.

On the other hand, closing the ash-pit door increases the draft throughout the setting and thereby increases the infiltration of cold air into the setting through cracks in the brickwork or openings in the furnace doors, and thus cools the products of combustion and increases the flue-gas losses. When the amount of air passing up through the grates and fuel bed is reduced, the grate bars and the ash resting on them become overheated by conduction of heat from the fuel bed. This overheating melts the ash, forming clinker, and causes the grate bars to burn.

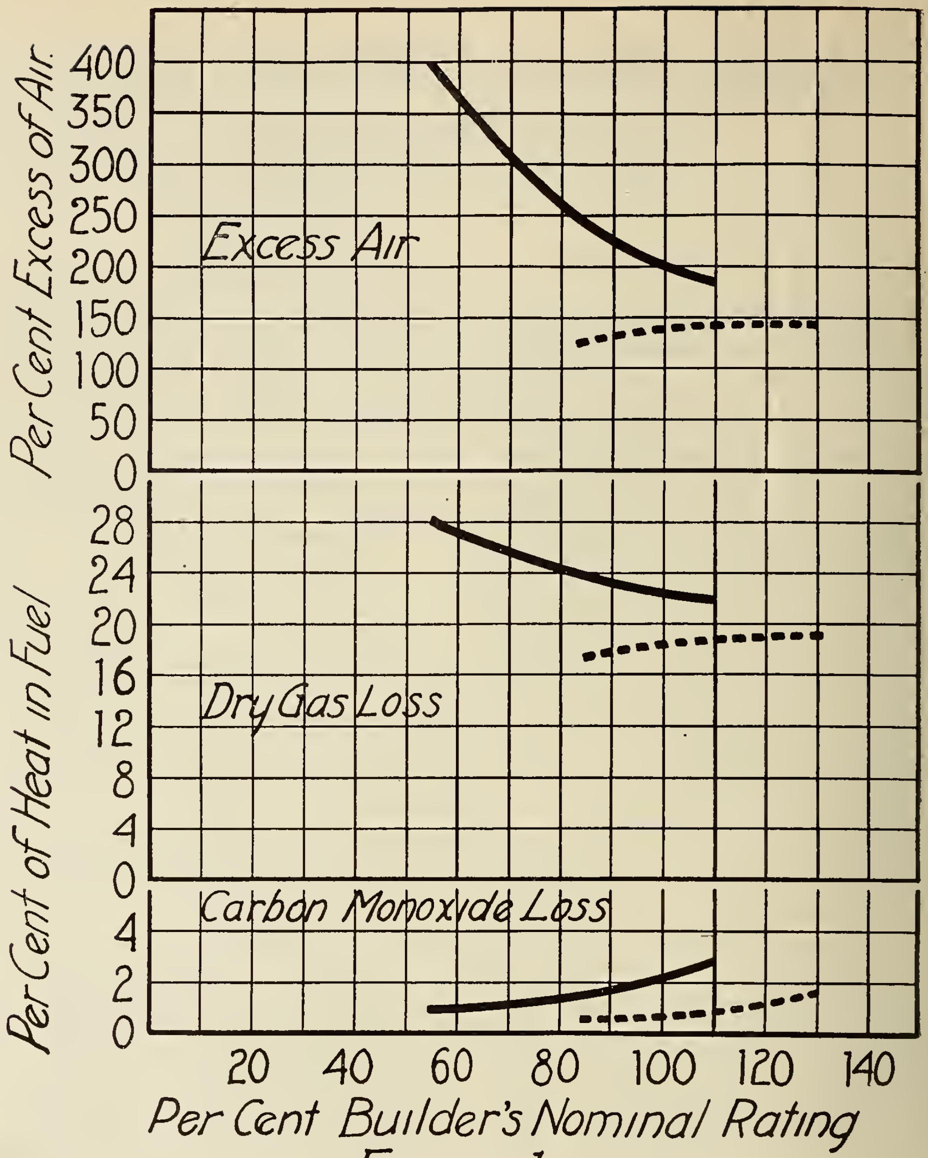

Figure 1.

Illustrate Gas Losses

In Figure 1 the flue-gas losses and excess air are plotted against boiler rating for two methods of boiler control. The solid curves show the variation in gas losses and excess air when the boiler was controlled by the ash-pit doors, and the dotted curves show the variation in gas losses and excess air when the boiler was controlled by the damper.

The difference in heat loss due to the presence of carbon monoxide in the flue gases, shown in the bottom set of curves, is not wholly due to the method of control of the boilers, but to a combination of the method of control, the furnace modifications, and the method of firing. The effect of the increased mixing action is perhaps most important in the reduction of this loss due to carbon monoxide.

The trend of both curves is similar, but the solid curve is higher at all ratings, and the loss increases far more rapidly as the rating increases under the original conditions than it does under the modified conditions.

Method of Control

The difference in heat loss due to the temperature and composition of the dry flue gases, shown in the middle section of the chart, is due almost entirely to the method of control of the boilers. The curves are similar in only one respect, and that is, they tend to become parallel to the base line as the rating increases. The solid curve, showing the dry-gas loss when the boiler was controlled by the ash-pit doors, rises rapidly with a decrease in rating; whereas the dotted curve, showing the dry-gas loss when the boiler was controlled by the damper, is more nearly level, and descends, as the rating decreases. The probable reason for the separation of the curves at higher ratings is in the improvements made in the method of firing which was more regular under the improved conditions, and consequently reduced the fluctuations in the proportion of air to combustible gas.

The curves showing the variation in the per cent. excess of air for the two methods of control are similar to the corresponding curves of dry-gas loss. The solid curve rises very rapidly as the rating decreases, whereas the dotted curve descends as the rating decreases.

In general, with ash-pit door control practically the same draft at the breeching is available at all rates of combus-

TABLE 1—TIME SPENT BY FIREMAN IN VARIOUS OPERATIONS.

Test No.	Rate of Working Boiler Per Cent.	Time Spent on Firing Minutes	Time Spent on Cleaning Minutes	Time Spent on Levelling Minutes	Time Spent on Barring Minutes	Total Time Spent During 12-hr. Test Minutes	Time spent on boiler per 1000 lb. of steam produced Minutes.	Kind of Fuel Used
1	71	23.34	35.92	0	0	59.26	2.38	Anthracite
2	79	33.08	42.25	0	0	75.33	2.75	do

tion, but that part of the available draft utilized for actual combustion decreases with the rate of working the boiler. The excess of draft over that utilized for combustion draws air into the furnace and setting above the grates, thus increasing the excess of air and dry-gas losses as shown. With damper control the available draft is reduced by shutting the damper so that the draft available to the boiler is enough for the desired rate of combustion only, and no excess exists to increase the stack losses.

Amount of Work

Perhaps the best criterion which can be used to judge the practicability of a firing method, from the standpoint of the fireman, is the amount of work he must do to produce a given amount of steam. If a new method requires more actual work on the part of a fireman, it is very likely that the method will be opposed, but if the fireman can be convinced that the new method requires no more work, and perhaps less work, it will be more readily acceptable.

In order to determine whether a fireman had to perform more actual work per 1,000 lb. of steam produced when he fired according to an improved method than when he fired without any attempt at regularity and without care, a record was kept on each test of the time spent on the various operations for each of the tests made.

Table gives a summary of the total time spent by the fireman on each of the various operations concerned with the fires.

The average work in minutes required of a fireman per 1,000 lb. of steam produced with anthracite is 2.69 minutes; with bituminous coal, under former plant operation, 1.98 minutes; and with bituminous coal, with the new firing method, 1.94 minutes.

To produce steam with anthracite requires more work than with bituminous coal, because the anthracite contains more ash and has a lower heating value per pound than bituminous coal. The higher ash content of anthracite necessitates more frequent cleaning, and on account of the lower heating value a larger quantity must be fired to produce 1,000 lb. of steam.

New Firing Method

The new method of firing requires approximately the same actual work per 1,000 lb. of steam produced as did the former method with bituminous coal as fuel. However, the new method also requires supervision until the firemen become accustomed to firing small amounts regularly, and to keeping their fires in good condition at all times.

This supervision is the price to be paid for more complete combustion without objectionable smoke, and is equivalent to a saving of $0.0685 or 16 per cent. in the cost of fuel per 1,000 lb. of steam. The time spent on levelling the fires is at least as much as that spent on firing, because this work is essential to good efficiency. It is the levelling of a fire which insures even combustion, for in this operation holes in the fire bed are covered and the coke bed is loosened so that combustion takes place more evenly. The observations of the smoke produced showed that barring a fire generally produced objectionable smoke, whereas levelling a fire from the top with a rake did not produce objectionable smoke. Even with a rake, however, smoke can be produced if the fireman is allowed to force the rake too deeply into the fuel bed.

A safe method of operation as regards smoke abatement is to use the rake for breaking and levelling the top of the fire without disturbing that portion resting on the grates. The grates themselves should be kept free from ash obstruction by running a flat hook over them at intervals of four hours. This hooking of the fires does not disturb the fuel bed to any great extent, but does keep the air passages in the grate bars open.

The improved firing method utilized the alternate system of firing. Thus only one-half of the grate surface is charged with green fuel at any one time, and the remaining half is left covered with a bed of freely burning incandescent coke from the preceding firing. In this way the fluctuation in furnace temperature is reduced and a temperature high enough to ignite the mixture of combustible gases and air, in the furnace, is maintained.

The procedure followed was to charge with fuel that portion of the fire reached through one of the fire doors and to break and level the other half as part of the same operation.

In order to determine the performance of the plant both before and after the modifications in the setting and control were introduced, a series of tests at different rates of evaporation per hour were made. Six tests, three with anthracite and three with bituminous coal, were made under the original conditions. After the conditions had been modified three more tests were run with bituminous coal, to determine the actual improvement in efficiency.

Table 2 represents the heat balances of the whole series of tests. Tests 1, 2 and 3, represent plant operation with anthracite; Tests 4, 5 and 6 represent plant operation with bituminous coal; and Tests 8, 9 and 10 represent modified operation with bituminous coal.

The principal features of the results obtained with anthracite are shown by the variation in efficiency, dry-gas loss, and ash-pit refuse loss, with rating. The efficiency and dry-gas losses decrease as the rating increases, while the loss in the ash-pit refuse tends to increase with the rating. The large ash-pit losses are due to the high ash content in the original coal which necessitated frequent cleaning of fires. It was found that steam could not be supplied in sufficient quantities if the fires were permitted to burn more than four hours without cleaning, so that the high ash-pit loss was part of the cost chargeable to smoke abatement under the original operating conditions.

The decrease in dry-gas losses with increase in rating further discredits control of boilers by ash-pit doors instead of by dampers, for the decreasing loss indicates that the available draft was more completely utilized for combustion as the rate of burning coal increased.

Under the original operating conditions with bituminous coal the efficiency

TABLE 2—PERFORMANCE FIGURES BEFORE AND AFTER.

	Before Modification						After Modification		
Number of trial	1	2	3	4	5	6	8	9	10
Kind of coal	Anthracite			Bituminous			Bituminous		
Per cent. of builder's rating %	71	79	63	107	81	56	125	99	85
Heat Balance per lb. Coal—As Rec'd.									
Heat absorbed by water %	57.9	55.7	58.9	66.0	61.0	59.0	66.5	65.7	69.0
